Structured condition, SUSTAIN necessarily learns all of the pairwise correlations because of the way clusters are updated (i.e., three clusters are formed that capture the three basic subtypes of stimuli). This type of learning in the Structured condition is what lead to the higher accuracy levels.

SUSTAIN's solution to Experiment 3 suggests some novel predictions: (a) When correlations are not interrelated, learning one correlation should block the learning of other correlations, and (b) When correlations are interrelated, either all of the correlations are learned or none of the correlations are learned. These predictions are explored in the following section.

Testing the Predictions In the original Billman and Knutson article, accuracy was considered in aggregate for all three correlations. Here, we reanalyze Billman and Knutson's data by considering each subjects' performance on each correlation (i.e., each subject contributes three scores to the analysis instead of one). SUSTAIN predicts that human subjects will learn only one of the three correlations in the Orthogonal condition, but will learn either all or none of the correlations in the Structured condition. If this is true, the mean variance of subjects' accuracies for the three correlations should be higher in the Orthogonal condition than in the Structured condition. This was indeed the case. The mean variance of each subject's three accuracy scores was 0.030 for the Orthogonal condition, but only 0.010 in the Structured condition ($t(46) = 2.76, p < .001$).

Discussion Due to the way SUSTAIN organizes its clusters, it predicts that learning one correlation in the Orthogonal condition blocks the learning of other correlations (which should result in a high within subject variance), whereas in the Structured condition learning one correlation is tied to learning all three correlations (which should result in a low within subject variance). These predictions were made prior to obtaining access to Billman and Knutson's data. The combined results of the original Billman study and the subsequent analysis, suggest that people find categories that are organized around highly correlated features to be easier to learn because correlations enable the transfer of knowledge across features. The mechanism that supports this operation may bare a strong resemblance to SUSTAIN.

Modeling Sorting Behavior with SUSTAIN

Billman and Knutson's (1996) studies suggest that subjects prefer stimulus organizations in which the perceptual dimensions are intercorrelated. However, studies in category construction reveal a contrasting pattern — subjects tend to sort stimuli along a single dimension. This behavior persists despite the fact

Table 4: The logical structure of the perceptual dimensions in Medin et al. (1987) sorted in two ways. In the family resemblance table, the stimuli with a preponderance of 1's can be seen as forming one family, while the stimuli with a preponderance of 2's can be seen as forming a second family or covert category. In the one-dimensional sort table, the same stimuli items are grouped on the basis of a single dimension (the first dimension).

Family Resemblance		One-dimensional Sort	
1 1 1 1	2 2 2 2	1 1 1 1	2 2 2 2
1 1 1 2	2 2 2 1	1 1 1 2	2 2 2 1
1 1 2 1	2 2 1 2	1 1 2 1	2 2 1 2
1 2 1 1	2 1 2 2	1 2 1 1	2 1 2 2
2 1 1 1	1 2 2 2	1 2 2 2	2 1 1 1

that alternate organizations exist that respect the intercorrelated nature of the stimuli, such as an intercorrelated family resemblance structure (Medin, Wattenmaker, & Hampson, 1987).

SUSTAIN was applied to the sorting data from Medin et al.'s (1987) Experiment 1 in hopes of reconciling the apparently contradictory findings. In Experiment 1, subjects were instructed to sort ten stimuli into two equal sized piles. Stimuli were cartoon-like animals that varied on four binary-valued perceptual dimensions (head shape, number of legs, body markings, and tail length). The logical structure of the items is shown in Table 4. The basic finding is that subjects sort along a single dimension (the one-dimensional sort in Table 4) as opposed to sorting stimuli according to their intercorrelated structure (i.e., the family resemblance structure shown in Table 4).

In these simulations, SUSTAIN was constrained to create only two piles (i.e., clusters) like Medin et al.'s subjects. This was accomplished by preventing SUSTAIN from recruiting a third cluster. SUSTAIN was presented with the items from Table 4 for 10 random training blocks to mirror subjects' examination of the stimulus set and their ruminations as to how to organize the stimuli. To evaluate the performance of the model, we looked at how SUSTAIN's two clusters were organized. Using the same parameters that were used in the Billman and Knutson (1996) studies listed in Table 3, SUSTAIN correctly predicted that the majority of sorts (99%) are organized along one stimulus dimension.

SUSTAIN's natural bias to focus on a subset of stimulus dimensions (which is further stressed by the selective attention mechanism) led it to predict the predominance of one-dimensional sorts. Attention is directed towards stimulus dimensions that consistently match at the cluster level. This leads

to certain dimensions becoming more salient over the course of learning (i.e., the model's attention value along that dimension becomes larger). The dimension that develops the greatest salience over the course of learning becomes the basis for the one-dimensional sort.

Which dimension provides consistent information during the course of learning will, in part, be determined by the order in which the stimulus items are presented to the model. Thus, SUSTAIN predicts that the order of card consideration in a sorting task might constrain which dimension human subjects focus their sort on. If card ordering has no effect and subjects randomly choose a dimension to sort on or choose due to individual differences in the salience of a particular dimension, then SUSTAIN's account should be insufficient.

Testing the Prediction

The following study tests this prediction by creating a modified version of the Medin, et al. sorting experiment in which the order that subject may consider cards is manipulated. Our interest was to test if the dynamics that led SUSTAIN to choose a particular dimension to sort on were the same dynamics that constrained subjects' sorting strategies.

Procedure Stimuli in our experiment were geometric shapes, printed on laminated cards, that varied on four of five binary valued dimensions (one dimensions value was held constant and thus had no influence on subjects sorting decisions). The dimensions were size (big or small), color of border (white or yellow), main color (blue or purple), a slash across the shape (present or absent), and texture (smooth or rough). Each dimension is independent and equally salient (as verified by multi-dimensional scaling of subjects' pairwise similarity ratings).

Participants were given a large board that was divided in half with a dark line (see Figure 1). Each side of the board had five positions in which to place cards. Before the start of an experiment trial, two "guide" cards were placed on the board that had opposing values along each dimension. Figure 1 shows an empty board with the abstract structure of these two guide cards. The particular values and meaning of each stimulus dimension was random for each subject (i.e., the values of the stimulus dimensions such as size and color were randomly assigned to one column of the abstract structure shown).

During the experiment, participants were given one new card at a time by the experimenter and were asked to place the card in an empty position on one side of the board according to what seemed most natural or sensible given the other cards on that side. The first two cards actually handed to subjects were constrained so that they mismatched on one dimension from the guide cards already on the board. For example, given the two cards in Fig-

Figure 1: The layout and initial configuration of the board given to subjects is shown.

ure 1 the abstract structure of the first two cards actually handed to the subjects might be $[0\ 0\ 0\ 1]$ and $[1\ 1\ 1\ 0]$.

The final 6 cards given to subjects were drawn from the remaining possible. Cards were randomly chosen but came in pairs of opposing values. For example, if the fourth card had the abstract structure $[0\ 0\ 1\ 0]$, the fifth might be $[1\ 0\ 1\ 1]$. This manipulation also helped to encourage subjects to fill the board up in a more or less even fashion rather than filling up one side completely, then having no choice as where to place the remaining cards.

Our hypothesis was that subjects would, like SUSTAIN, place the first two cards on the board on the basis of overall similarity to the guide cards as opposed to randomly choosing a single dimension on which to focus their sorting strategy. Thus in our example, $[0\ 0\ 0\ 1]$ would be placed under the $[0\ 0\ 0\ 0]$ prototype and $[1\ 1\ 1\ 0]$ would be placed under the $[1\ 1\ 1\ 1]$ prototype. If subjects allocated attention to dimensions that provide consistent information like SUSTAIN, then attention would be increased on only the dimensions that matched the guide cards (all but the fourth dimension in this case). This initial attentional disadvantage on the fourth, mismatched dimension would prevent subjects from sorting on that dimension.

Results Twenty-eight psychology undergraduate students participated in the study for course credit. The results collected for this study are shown in Table 5. Of the 28 subjects, 23 subjects performed a one-dimensional sort while 5 used an alternate sorting strategy. Of the 23 subjects that performed a one dimensional sort, only 2 of these 23 subjects sorted the cards using the mismatched dimension as their basis for organization. If subjects had no particular preference for any dimension and the manipulation of the cards had no effect, then the probability of getting 21 out of 23 subjects to sort on a dimension other than the one mismatching dimension is

Table 5: The results of the sorting study.

	Number of Subjects
Subjects using a 1D sort	23
--Mismatched Dimension	2
--Other Dimensions	21
Subjects using a non 1D sort	5
--Family Resemblance	3
--Unknown Strategy	2
Total Subjects	28

less than .05 as given by a two-tailed binomial trial ($n=23$, $p = .25$). Of the five subjects that did not perform a one-dimensional sort, three performed a family resemblance sort and two performed a sort using an undecipherable sorting strategy.

SUSTAIN was simulated using the same parameters used for the Billman and Knutson studies (Table 3) and using the same conditions from the Medin, et al. sorting simulation, but with the specific card orderings that subjects were given in our experiment. In 100% of the trials, the model used a dimension other than the mismatched dimension as the basis for a one-dimensional sort.

Discussion

The dimension that subjects choose to sort in this task cannot be explained as random choice. The results presented in our experiment provide evidence that the order of card presentation plays a role in influencing subjects to sort on a particular dimension.

Specifically, sorting behavior is influenced by the way we perceive similarity between stimuli. In this unsupervised task, attention is allocated such that the similarity space changes during the course of learning. At the start of learning, each dimensions is more or less equally important, but as learning proceeds, certain dimensions become more salient (because they are more informative) while others become less. This warping of the similarity space is what ultimately causes judgments in this type of task to become based on a single dimension, rather than on the overall similarity between items. The fact that SUSTAIN predicted this behavior gives additional support to the notion that it's principles reflect some of the true operational principles of human learning.

Conclusions and Implications

SUSTAIN's combined account of Billman and Knutson's (1996) studies and Medin et al. (1987) suggest that the salience of stimulus dimensions change as a result of unsupervised learning and that the correlated structure of the world is more likely to be respected when there are numerous intercorrelated dimensions that are strong. In cases where the total

number of correlations is modest, and the correlations are weak and not interrelated (such as in the Medin et al. stimuli), SUSTAIN predicts that stimuli will be organized along a single dimension.

The ability of SUSTAIN to account for two diverse unsupervised learning data sets with a single set of parameters demonstrate how it's formulation positions it as a robust model of category learning. In addition to the studies reported here, SUSTAIN's principles has been shown to generalize across a number of other forms of category learning (such as supervised learning and inference learning). It is these well-defined principles and the transparent operation of SUSTAIN that allow it to make the two predictions which have been successfully confirmed here.

Acknowledgments

We would like to offer our sincere thanks to Dorrit Billman for providing access to her data and to Rob Goldstone for motivating the sorting study. This work was supported by AFOSR Grant F49620-01-1-0295.

Abstract

Following up on previous work by Thagard (1989, 2000) we have developed a connectionist constraint satisfaction model which aims at capturing a wide variety of tasks involving causal cognitions, including causal reasoning, learning, hypothesis testing, and prediction. We will show that this model predicts a number of recent findings, including asymmetries of blocking, and asymmetries of sensitivity to structural implications of causal models in explicit versus implicit tasks.

Introduction

Causal reasoning has been widely investigated during the last decade, which has led to a number of interesting novel findings (see Shanks, Holyoak, & Medin, 1996; Hagmayer & Waldmann, 2001, for overviews). For example, it has been shown that participants' causal judgments are sensitive to the contingency between the cause and the effect, and that people's judgments reflect the causal models underlying the observed learning events (see Hagmayer & Waldmann, 2001; Waldmann, 1996). Moreover, causal reasoning has been studied in the context of a number of different tasks, such as learning, reasoning, categorization, or hypothesis testing.

Most psychological theories and computational models of causal learning and reasoning are rooted in two traditions. They are either based on associationistic or on probabilistic or Bayesian models (see Shanks et al., 1996; Thagard, 2000). Both kinds of models have been criticized. Associationistic learning networks have proven unable to capture the fundamental semantics of causal models because they are insensitive to the differences between learning events that represent causes versus effects (see Waldmann, 1996). By contrast, Bayesian networks are perfectly capable of representing causal models with links directed from causes to effects (see Pearl, 2000). However, although the goal of these networks is to reduce the complexity of purely probabilistic reasoning, realistic Bayesian models still require fairly complex computations, and they presuppose competencies in reasoning with numerical probabilities which seem unrealistic for untutored people (see Thagard, 2000, for a detailed critique of these models).

The aim of this paper is to introduce a more qualitatively oriented, connectionist constraint satisfaction model of causal reasoning and learning. Our model is inspired by Thagard's (2000) suggestion that constraint satisfaction

models may qualitatively capture many insights underlying normative Bayesian network models in spite of the fact that constraint satisfaction model use computationally far simpler, and therefore psychologically more realistic processes. The model differs from standard associationist learning models (e.g., Rescorla & Wagner, 1972) in that it is capable of expressing basic differences between causal models. Our model embodies a uniform mechanism of learning and reasoning, which assesses the fit between data and causal models. This architecture allows us to model a wide range of different tasks within a unified model, which in the literature have so far been treated as separate, such as learning and hypothesis testing.

Constraint Satisfaction Models

Constraint satisfaction models (Thagard, 1989, 2000) aim at capturing qualitative aspects of reasoning. Their basic assumption is that people hold a set of interconnected beliefs. The beliefs pose constraints on each other, they either support each other, contradict each other, or are unrelated. Coherence between the beliefs can be achieved by processes which attempt to honor these constraints.

Within a constraint satisfaction model beliefs are represented as nodes which represent propositions (e.g., "A causes B"). The nodes are connected by symmetric relations. The numerical activation of the nodes indicates the strength of the belief in the proposition. A belief that is highly activated is held strongly, a belief that is negatively activated is rejected. The activation of a node depends on the activation of all other nodes with which it is connected. More precisely, the net input to a single node j from all other nodes i is defined as the weighted sum of the activation a of all related nodes (following Thagard, 1989, p.466, eq.5):

$$\text{Net}_j = \sum_i w_{ij}a_i(t) \quad (1)$$

The weights w represent the strength of the connection of the beliefs. In our simulations, they are generally pre-set to default values which are either positive or negative and remain constant throughout the simulation. At the beginning of the simulations, the activation of the nodes representing hypotheses are set to a low default value. However, nodes representing empirical evidence are connected to a special activation node whose activation remains constant at 1.0. This architecture allows us to capture the intuition that more faith is put into empirical evidence than into theoretical hypotheses (see Thagard, 1989). To update the activation in each

cycle of the simulation, first the net input net_i to each node is computed using Equation 1. Second the activation of all nodes is updated using the following equation (Thagard, 1989, p.446, eq.4):

$$a_i(t+1) = a_i(t)(1-\theta) + net_i(\max - a_i(t)) \text{ if } net_i > 0 \\ = a_i(t)(1-\theta) + net_i(a_i(t) - \min) \text{ otherwise.} \quad (2)$$

In Equation 2, θ is a decay parameter that decrements the activity of each node in every cycle, \min represents the minimum activation (-1) and \max the maximum activation (+1). The activations of all nodes are updated until a stable equilibrium is reached, which means that the activation of all nodes do no longer substantially change. To derive quantitative predictions it would be necessary to specify rules that map the final activations to different types of responses. This is an important goal which should be addressed in future research. In the present article we only derive ordinal, qualitative predictions from the model.

The Model

Following causal-model theory (Waldmann, 1996) we assume that people typically enter causal tasks with initial assumptions about the causal structure they are going to observe. Even though specific knowledge about causal relations may not always be available, people often bring to bear knowledge about abstract features of the models, such as the distinction between events that refer to potential causes and events that refer to potential effects. In virtually all psychological studies this information can be gleaned from the initial instructions and the materials (see Waldmann, 1996).

Figure 1 displays an example of how the model represents a causal model. The nodes represent either causal hypotheses or observable events. The causal hypothesis node at the top represents a structural causal hypothesis (H1), in this case the hypothesis that the three events e_1 , e_2 , x form a common-effect structure with e_1 and e_2 as the two alternative causes and x as the common effect. The two nodes on the middle level refer to the two causal relations H2 and H3 that are part of the common-effect model with two causes and a single effect. The nodes on the lowest level refer to all patterns of events that can be observed with three events (a dot represents "and"). On the left side, the nodes represent patterns of three events, in the middle pairs, and on the right side single events. Not only the present but also the corresponding absent events are represented within this model (for example $\sim x$). The links connecting the nodes represent belief relations. Thus, they do not represent probabilities or causal relations as in Bayesian models. There are two different kinds of connections between the nodes. Solid lines indicate excitatory links, dashed lines inhibitory links. How are the connections defined? A connection is positive if the propositions support each other. For example, if all three events are present, the observation is in accordance with both hypotheses H2 and H3. This pattern might be observed if both e_1 and e_2 cause x . Therefore the evidence node $e_1.e_2.x$ is positively connected to H2 and H3. In general, a hypothesis is positively connected to an evidence node if the events mentioned in the hypothesis are either all present or all absent. If this is not the case, that is if one of the relevant events specified in the hypothesis is absent, the link is as-

signed the negative default value. Exploratory studies have shown, that participants share a common intuition whether a certain pattern of events supports or contradicts a hypothesis (Hagmayer & Waldmann, 2001). The assigned weights mirror these general intuitions. The weights of the links remain the same throughout the simulations. Figure 1 does not display the special activation node. This node was pre-set to 1.0 and attached to event nodes describing present events in the respective experiment.

Figure 1: Constraint satisfaction model of causal learning and reasoning. See text for further explanations.

In Figure 1, the dashed line between the hypotheses H1 and H2, which signifies an inhibitory link, is of special interest. The network represents a common-effect structure. This means that there are two causes e_1 and e_2 which compete in explaining the occurrence of effect x . Therefore the two hypotheses referring to the individual causal relations have to be connected by an inhibitory link (see also Thagard, 2000). However, both hypotheses H2 and H3 are positively connected to the structural hypothesis H1. By contrast, a common-cause structure is represented slightly differently. In such a structure, event x would be the common cause of the two effects e_1 and e_2 (i.e., $H1: x \rightarrow e_1.e_2$). A model of this structure looks almost identical to the one for the common-effect structure in Figure 1. There is only one very important difference. Because there is no competition between the effects of a common cause, a common-cause model has no inhibitory link between H2 and H3. All other nodes and links in the two models are identical.

Both the common-effect and the common-cause model were implemented using Microsoft Excel. Default values were adopted from the literature if not indicated otherwise (Thagard, 1989). Initial activations were set to 0.01, inhibitory links between nodes to -0.05, and excitatory links to +0.05. The inhibitory link between H1 and H2 within the common-effect model was pre-set to a value of -0.20. The

special activation node was attached to all evidence nodes. The additional activation was divided among the evidence nodes according to the relative frequency of the evidence in the learning input. This principle captures the intuition that more faith is put into evidence that is observed more frequently.

Evaluation

In order to evaluate the proposed constraint satisfaction model different tasks and paradigms from the literature on causal learning and reasoning were modeled. One of our main goals was to show that the same architecture can be used to simulate different types of tasks. However, different tasks required different sections of the model depicted in Figure 1. We used two principles for the construction of task specific networks. The first principle is that we only included the event nodes that corresponded to the event patterns observed in the learning phase or that corresponded to events that have to be evaluated or predicted in the test phase. For example, to model a task in which only event triples were shown, only the event nodes on the left side of the event layer in Figure 1 would be incorporated in the model. However, if the task following the learning phase required the prediction of single events, the corresponding nodes for single events would have to be added to the event layer. The second principle is that only the hypothesis nodes were included that represent hypotheses that are given or suggested to participants. These two principles ensure that for each paradigm a minimally sufficient sub-model of the complete model is instantiated.

Test 1: Asymmetries of Blocking

Blocking belongs to the central phenomena observed in associative learning which, among other findings, have motivated learning rules that embody cue competition (e.g., Rescorla & Wagner, 1972). A typical blocking experiment consists of two learning phases. In Phase 1 participants learn that two events e_1 and x are either both present or absent. In Phase 2 a third event e_2 is introduced. Now all three events are either present or absent. In both phases, events e_1 and e_2 represent cues and x the outcome to be predicted. Associative theories generally predict a blocking effect which means that participants should be reluctant about the causal status of the redundant event e_2 that has been constantly paired with the predictive event e_1 from Phase 1. This prediction has come under attack by recent findings that have shown that the blocking effect depends on the causal model learners bring to bear on the task (see Waldmann, 1996, 2000). If participants assume that e_1 and e_2 are the causes of x (common-effect structure) a blocking effect can be seen. In contrast, if participants assume that e_1 and e_2 are the collateral effects of the common cause x (common-cause structure), no blocking of e_2 is observed. In this condition, learners tend to view both e_1 and e_2 as equally valid diagnostic cues of x .

To model blocking, we used a network that was extended after Phase 1. In Phase 1, the net consisted of a hypothesis node (H_2) and the nodes for patterns of two events (e_1, x). After Phase 1, the final activation of the hypothesis node was transferred to Phase 2. In Phase 2, the network

consisted of two nodes for the two causal hypotheses (H_2 and H_3), and nodes that represented patterns of three events, the patterns participants observed within the learning phase. Furthermore, the node H_1 was included, which, depending on the condition, either coded a common-cause or a common-effect hypothesis. The nodes for the event pairs from Phase 1 were removed.

Figure 2 shows the activation of the two hypotheses referring to the causal relations in Phase 1 and 2. Figure 2A depicts the activation for the common-cause model and Figure 2B for the common-effect model.

Figure 2A: Simulation of a blocking paradigm (Test 1). Activation of hypothesis nodes for a common-cause model. The solid line represents the activation of $H_2: x \rightarrow e_1$, the dotted line of $H_3: x \rightarrow e_2$. Phase 2 started at the 101st cycle.

The model shows no blocking for event e_2 in the context of the common-cause model. It quickly acquires the belief that there is a causal connection between x and e_2 .

Figure 2B: Simulation of a blocking paradigm (Test 1). Activation of hypothesis nodes for a common-effect structure. The upper line represents the activation of $H_2: e_1 \rightarrow x$, the lower line of $H_3: e_2 \rightarrow x$. Phase 2 started at the 101st cycle.

For the common-effect model the simulation shows blocking of the second cause, that is the second hypothesis is believed to be wrong. Thus, the simulations closely correspond to the empirical finding that blocking interacts with the structure of the causal model used to interpret the learning data.

Test 2: Testing Complex Causal Hypotheses

The first test of the model used a phenomenon from the literature on causal learning. We now want to turn to a completely different paradigm, hypothesis testing. In experiments on causal learning participants are typically instructed about a causal structure, and the task is to learn about the causal relations within the structure. They are not asked whether they believe that the structure is supported by the learning data or not. In recent experiments (Hagmayer, 2001; Hagmayer & Waldmann, 2001) we gave participants the task to test a complex causal model hypothesis. For example, we asked them whether three observed events support a common-cause hypothesis or not. Normatively this task should be solved by testing the implications of the given structural hypothesis. For example, a common-cause model implies a (spurious) correlation of the effects of the single common cause. In contrast, a common-effect structure does not imply a correlation of the different causes of the joint effect. Unless there is an additional hidden event that causes a correlation among the causes, they should be uncorrelated. In the experiment, participants were given data which either displayed a correlation between all three events (data set 1) or correlations between $e1-x$ and $e2-x$ only, that is $e1$ and $e2$ were marginally independent in this data (data set 2). Data set 1 was consistent with a common-cause hypothesis which implies correlations between all three events. In contrast, data set 2 favors the common-effect hypothesis with x as the effect and $e1$ and $e2$ as independent causes. However, in a series of experiments we found that participants were not aware of these differential structural implications when testing the two hypotheses. Instead they checked whether the individual causal relations within the complex structures held (e.g., $e1-x$). Thus, participants dismissed a hypothesis if one of the assumed causal links was missing. However, they proved unable to distinguish between the common-cause and the common-effect structure when both structures specified causal connections between the same events (regardless of the direction).

To model this task we used the model without the nodes for event pairs and individual events. The special activation node was connected to the patterns of three events. As before the activation of the individual event patterns was proportional to the frequency of the respective pattern in the data. To test the model, we used three sets of data. Either all three events were correlated (data set 1), $e1$ and x , and $e2$ and x were correlated and $e1$ and $e2$ were marginally independent (data set 2), or $e1$ and x , and $e1$ and $e2$ were correlated, and $e2$ and x were uncorrelated (data set 3). As competing hypotheses we either used a common-cause model with x as the common cause, or a common-effect model with x as the common effect. Figure 3 shows the activation of the node H1 which represents the hypothesis that the respective causal model underlies the observed data.

Figure 3A shows the results for the common-cause hypothesis, Figure 3B for the common-effect hypothesis. The results clearly mirror the judgments of our participants. Whenever the two assumed causal relations within either causal model were represented in the data, the structural hypothesis was accepted (solid lines), if one link was missing the hypothesis was rejected (dotted line).

One slight deviation from our empirical findings was observed. In early cycles there seems to be an effect favoring the common-effect hypothesis with data consistent with this hypothesis. However, the difference between the hypotheses is relatively small and further decreases after 100 updating cycles. Thus, the results are consistent with participants' insensitivity to structural implications of causal models in hypothesis testing tasks.

Figure 3A: Activation of hypothesis node H1 for a common-cause model (Test 2). The solid lines represent the activations for data set 1 and 2, the dotted line the activations for data set 3.

Figure 3B: Activation of hypothesis node H1 for a common-effect model (Test 2). The solid lines represent the activations for data set 1 and 2, the dashed line at the bottom the activations for data set 3

Why does the model not differentiate between the two causal structures? The reason is that it is assumed that complex structural hypotheses are not directly linked to empirical evidence. In our model empirical evidence is connected to the hypotheses that represent individual causal links which in turn are linked to more complex model-related hypotheses. This architecture allows it to model learning and hypothesis testing within the same model. It also seems to capture the empirical finding that participants can easily decide whether a certain pattern of events supports a simple causal hypothesis, but have a hard time to relate event patterns to complex causal hypotheses.

Test 3: Causal Inferences

In the previous section we have mentioned studies showing insensitivity to spurious relations implied by causal models. A last test for our model is a task in which participants have to predict other events under the assumption that a certain causal model holds. Interestingly we have empirically demonstrated sensitivity to structural implications of causal models in this more implicit task (Hagmayer & Waldmann, 2000). In this task participants do not have to evaluate the validity of a causal model in light of observed evidence but rather are instructed to use causal models when predicting individual events. In our experiments we presented participants with two learning phases in which they learned about two causal relations one at a time. Thus, in each phase participants only received information about the presence and absence of two events (x and $e1$, or x and $e2$). They never saw patterns of all three events during the experiment. The initial instructions described the two causal relations, which were identically presented across conditions, either as parts of a common-cause model with x as the cause or as part of a common-effect model with x as the effect. After participants had learned about the two causal relations we asked them to predict whether $e1$ and $e2$ were present given that x was present. We found that participants were more likely to predict that both $e1$ and $e2$ would co-occur when x was viewed as the common cause than when it was seen as a common effect. Thus, in this more implicit task the predictions expressed knowledge about structural implications of causal models. In particular, the patterns the participants predicted embodied a spurious correlation among the effects of a common cause, whereas the causes of a common effect tended to be marginally uncorrelated in the predicted patterns. By contrast, in a more direct task which required explicit judgments about correlations, no such sensitivity was observed, which is consistent with the results reported in the previous section.

To model this experiment we eventually used the complete network depicted in Figure 1 which was successively augmented according to our two principles. In Phase 1, the learning phase, patterns of two events were connected to the hypotheses H2 and H3. Depending on the learning condition, these two hypotheses were either linked to a common-cause or a common-effect hypothesis (H1). The activations of the hypothesis nodes at the end of Phase 1 were used as initial activation values in Phase 2. In Phase 2 the model consisted of the three hypothesis nodes, the nodes for patterns of three events and the nodes representing single events. The single event nodes were included because the task required the prediction of individual events. The special activation node was now attached to event x . The model then predicted the other two individual events and patterns of all three events.

The model quickly learned the causal relations during Phase 1 of the experiment. Figure 4 depicts the results of Phase 2. Figure 4A shows the predictions of the model for the condition in which participants assumed a common-cause model, Figure 4B shows the results for the common-effect condition. The results of the simulations are consistent with the behavior we have observed in our participants. When the model assumes a common-cause model the pres-

ence of x leads to a high positive activation of the two effects $e1$ and $e2$. This means that the model tends to prefer the prediction that the two effects of a common cause co-occur. In contrast, for the common-effect structure the model does not show such a preference. In this condition, both causes or either one of them equally qualify as possible explanations of the observed effect. This means that our model, similar to the one Thagard (2000) has proposed, tends to "explain away" the second cause when one of the competing causes is present. This is a consequence of the competition between the two causal hypothesis H2 and H3.

Figure 4A: Implicit causal inferences (Test 3). Activation of single event nodes for the common-cause model: Event x (top), events $e1$ and $e2$ (bottom)

Figure 4B: Implicit causal inferences (Test 3). Activation of single event nodes for the common-effect model: Event x (top), event $e1$ (middle), event $e2$ (bottom)

Discussion

A constraint satisfaction model of causal learning and reasoning was presented in this paper that extends the architecture and scope of the model proposed by Thagard (2000). Thagard's model focuses upon causal explanations of singular events and belief updating. Our aim was to create a model that allows it to model both learning and reasoning within causal models. The model was successfully applied to three different tasks. It modeled people's sensitivity to structural implications of causal models in tasks involving learning and predictions whereas the same model also predicted that people would fail in tasks which required explicit knowledge of the statistical implications of causal models.

One question that might be raised is whether the proposed model really captures learning or just models causal judgment. In our view, the concept of learning does not necessarily imply incremental updating of associative weights. Our model embodies a hypothesis testing approach to learning which assumes that learners modify the strength of belief in deterministic causal hypotheses based on probabilistic learning input. This view also underlies recent Bayesian models of causality (Pearl, 2000). In the model the activation (i.e., degree of belief) of the hypothesis nodes is modified based on the learning input. This way the model is capable of modeling trial-by-trial learning as well as learning based on summary data within the same architecture.

Thus far we have pre-set the weights connecting evidence and hypotheses. In our view, the assigned values reflect everyday qualitative intuitions about whether an event pattern supports or contradicts a hypothesized causal hypothesis. These weights remained constant throughout the simulations. Despite this restriction the model successfully predicted empirical phenomena in learning and reasoning. However, pre-setting these weights is not a necessary feature of the model. It is possible to add a learning component that acquires knowledge about the relation between event patterns and hypotheses based on feedback in a prior learning phase (see Wang et al., 1998, for a model adding associative learning to Echo).

In summary, our constraint satisfaction model seems to offer a promising new way to model causal learning and reasoning. It is capable of modeling phenomena in a wide range of different tasks, which thus far have been treated as separate in the literature. Relative to normative Bayesian models, our connectionist model allows it to simulate a large number of different tasks and different phenomena while using fairly simple computational routines. It proved capable of capturing a number of recent phenomena that have presented problems to extant models of causal cognition. More tests of the model clearly seem warranted.

Abstract

There is good theoretical reason to believe that the application of explicit rules does not proceed in a strictly context free manner, whereby the features stipulated by the rule are simply checked one by one. The fact that specifications of general knowledge seem inherently prone to exception suggests that a more flexible approach is required. One way of balancing the simplicity of rules with the need for flexibility is through the combination of rule application with the monitoring of instance-similarity. As a test of this hypothesis, this paper reports an experiment which examines effects of instance similarity on the speed with which a simple explicit rule can be applied, both as a function of experience with the rule and its complexity.

Introduction

Since its very beginnings Cognitive Science has sought to establish the role of rules in human cognition. However, this work has focussed primarily on *internal*, often implicit, rules. With this we mean rules which are internal to the cognitive system and typically unavailable for conscious inspection, and which have no external, public manifestation. Hence this work has had little to say about how we reason with external, explicit rules such as legal rules or explanatory rules provided in educational settings.

This state of affairs is highly unsatisfactory last but not least because evidence for internal rules has been harder to come by than cognitive scientists originally thought, with any claim for rule-based behaviour typically countered by alternative – most frequently similarity-based – explanations, and supposedly supporting data. By contrast, the existence of vast numbers of external rules is beyond doubt. How we reason with these should thus be a central concern.

We present here an experimental investigation of the way in which explicit rules are applied, examining specifically the role of similarity in this process.

General Background

Past research within cognitive psychology has sought evidence for internal rules in a wide range of domains, from language, to implicit learning, reading and problem-solving. Each of these areas has seen intensive debate between proponents of rule-based accounts and proponents of alternative, similarity-based explanations (see e.g., Hahn & Chater, 1998a for an overview). For example, categorization might be construed as the application of rules the learner has abstracted during learning (e.g., “If it is furry, four legged and barks, then the creature is a dog”) or similarity comparison to known exemplars or a prototype (e.g., “This creature is so similar to Lassie, that it must be a dog”). In this way, rules and similarity have typically been viewed in opposition.

However, detailed computational considerations – which draw lessons from Artificial Intelligence – suggest that neither purely rule-based reasoning, nor purely similarity-based reasoning are optimal or even feasible strategies for real-world tasks (Hahn & Chater, 1998a, 1998b; Oaksford & Chater, 1991). Such considerations lessen the plausibility of any cognitive account that seeks to explain human performance solely in terms of one or the other.

However, similarity- and rule-based reasoning differ in their respective strengths and weaknesses. Hence, computational considerations suggest that ‘blends’, which combine the strength of both, are an extremely interesting class of account (Hahn & Chater, 1998a, 1998b). This is reflected in a recent interest in hybrid experts systems within AI which encompass both rule and similarity-based components (e.g., Rissland & Skalak, 1991).

Furthermore, it is highly suggestive that law, next to science the single most elaborate and explicit system we have developed for dealing with every-day life, displays both similarity- and rule-based reasoning in the form of precedent and statute. While legal systems differ regarding the relative weight they place on each of these factors (e.g., the Anglo-American legal tradition emphasises similarity to past cases, and the continental tradition emphasises rules),

the 'blend' of both is a robust finding for all western legal systems.

Together, these considerations suggest that research might profitably turn toward studying the potential interplay between rules and similarity in human thought.

The particular way we propose to do this also turns away from the focus on internal rules to external rules which, as the examples of both law and educational instruction show, are of indisputable significance in human cognition.

Previous Research

In comparison to the wealth of research examining either rules or similarity (see Hahn & Chater, 1998a for references), the body of previous experimental research examining a possible *interplay* of rules and similarity is tiny (e.g., Ross, Perkins & Tenpenny, 1990; Allen & Brooks, 1991; Nosofsky, Palmeri and McKinley, 1994). Of this work, only two studies consider explicit, external rules that are given to participants by the experimenter -Nosofsky, Clark & Shin, 1989 and Allen and Brooks (1991). Both find effects of exemplar similarity in the context of rule application. This is first positive evidence for a routine interaction between similarity and the application of explicit rules as might seem desirable in the light of computational considerations. Further examination, however, is required. In particular, the Allen and Brooks (1991) study does not provide the most robust test of the hypothesis that similarity generally influences rule application. Allen and Brooks provided participants with an explicit rule by which a set of training stimuli could be perfectly classified. Despite the fact that the rule was perfectly predictive, i.e. sufficient for classification, and that participants were both aware of the rule and the instruction to use it, their performance on novel items was significantly affected by the test items degree of similarity to items seen during training. However, the nature of the rule used raises worries about the robustness and generality of their findings.

Crucially, the explicit rule used in the experiment defined a prototype. The use of similarity might conceivably be an (artefactual) result of this, rather than a property of rule application in general. Specifically, the rule used in the Allen & Brooks study had the form "if X has 3 of the 5 features {a,b,c,d,e}, then X is a category member". In other words, the rule specifies a so-called **m-of-n concept** and thus is formally equivalent to a prototype (n, i.e. an item with ***all*** relevant features present) and a threshold (m, i.e. the number of matching features required) which determines the degree of similarity to the prototype which items must have in order to be category members (Langley, 1994; Hahn & Chater, 1998a). This equivalence makes Allen and Brooks' similarity effects rather less surprising. The rule effectively defines a prototype plus similarity threshold, thus virtually suggesting the general use of similarity to participants. Thus, the fact that even similarities irrelevant from the perspective of the rule influenced classification, Allen and Brooks' finding, might have arisen only because the nature of the rule pointed toward similarity in the first place.

To establish more generally a role for similarity in rule application we need to repeat the basic Allen and Brooks study with a rule that does not involve the specification of a prototype. It is crucial to see what happens if the rule is something like "choose all symmetric patterns," or "all patterns that have an even number of corners". Does one still find effects of similarity to training items on classification speed and accuracy with such a rule?

The second limitation of the Allen and Brooks' study concerns rule complexity. The rule used by Allen and Brooks is a fairly complicated one, so that participants might conceivably have had difficulty operationalising it. Thus Allen and Brooks similarity effects might be the result of alternative, "fall-back" strategies on the part of the participants or of errors arising from failure to use the rule, and not—as we would like to see—the result of genuine interaction between rule and similarity-based processing.

This suggests that it is crucial to look also at asymptotic performance, (that is performance after several experimental trials), to see whether influences of previously seen exemplars disappear as participants' accuracy with the rule grows.

Our study seeks evidence for a constructive interplay of similarity and rule application which avoids these limitations. To this end we conduct a simple replication with a different type of rule, varying rule complexity, and monitoring asymptotic performance.

Experimental Investigation

Our materials were simple geometric shapes as depicted in Figure 1 below.

Figure 1: an example of a training material used in the experiment.

Category membership was governed by a simple, explicit rule "*is an A if it has an upside down triangle at the side*" in one-feature rule condition, and by a more complex rule, which made reference to three features —"*is an A if it has an upside down triangle at the sides, a cross in the centre, and a curly line at the top*"— in the complex rule condition. Neither of these constitute an m-of-n concept as did Allen & Brooks' rule. Testing and comparing both a simple and a more complicated rule would further allow us to ascertain the robustness of any putative similarity effect. Specifically, it would allow us to examine whether the similarity effects in the Allen & Brooks study were simply down to participants difficulties in operationalising the rule and, as a result, seeking out alternative, easier strategies.

To the same end, we also monitored participants' performance over four blocks of training—each of which comprised 24 exposures to the test stimulus items. This would allow us to examine whether similarity effects vanished as participants became more and more proficient with the rule.

At the heart of the study is its similarity manipulation. This was achieved by manipulating the additional features not referenced by the rule. Participants received a set of training items to illustrate the rule they had been provided with. The actual experimental test items were either high in similarity or low in similarity to these illustrative training items. The high-similarity test items differed from the training items in one feature; this feature was not referenced by the rule and consequently was irrelevant to the categorization task at hand. The low similarity items differed from the illustration items in 3 features, again features irrelevant to the application of the rule. Because the similarity manipulation concerned only stimulus aspects which were irrelevant to the rule, a difference in the way the high- and low-similarity items were treated would indicate an influence of similarity on the rule-based classification process, despite these differences in similarity being completely irrelevant to the application of the rule. This would provide evidence for an automatic monitoring and processing of similarity information in the context of rule application even where there were no task demands to necessitate this.

To make the classification task a genuine one, it was necessary to have both test items that complied with the rule and ones that didn't. The non-compliant test items, again, were either high- or low- similarity to the illustrative test items, differing from these items in a single feature which contradicted the rule, in the case of the high-similarity non-compliant items, or in a rule-feature and two further irrelevant features in the case of the low-similarity, non-compliant items. As a consequence, similarity effects could emerge both where the rule was applicable and where it did not apply.

The central prediction of this study was that there should be a difference in the speed with which the rule was applied between high- and low-similarity items. Specifically, compliant items which were also high in similarity to the training items should be classified more quickly than compliant items which were low in similarity. Differences should also emerge between the non-compliant high- and low-similarity items, though the direction of the difference is harder to predict here; low-similarity items might be rejected more quickly, but advantages at the decision-making stage are likely to be offset to greater or lesser extent by increased costs of processing a less familiar image. In addition, we would expect an effect of training on reaction time, and that the three feature rule should be slower to apply than the one feature rule because it requires a more complete scan of the stimulus, although these two predictions have no bearing on our experimental question.

With regards to similarity effects, we would also expect differences in the amount of errors elicited by high- and low-similarity items. Low-similarity compliant items, and

high-similarity non-compliant items expected to be more error prone than their counterparts.

Method

Participants

Ninety-one undergraduate students from the University of Bangor (Wales) participated in this experiment as an extra credit option in a Psychology course. 45 participated in the simple rule condition while 46 took part in the complex rule condition.

Materials

The stimuli were line drawings of geometric shapes that varied in 6 aspects: Body, Side Ears, Top/Bottom, Inner, Antenna, and Hair. There were six alternative realisations of each of these aspects. We generated a total of 108 stimuli: 12 training items and 96 test items. Figure 1 gives an example of a training material used in the experiment.

The 96 test items were composed of four different types of items which formed to four conditions: 24 high-similarity (C-High) and 24 low-similarity (C-Low) (items that complied with the rule), and 24 high-similarity (N-High) and 24 low-similarity (N-Low) (items that did not comply with the rule). High-similarity items differed from (one of the items of) the training set in one value. Low-similarity items differed from (one of the items of) the training set in three values. For the items that complied with the rule, the differed value was always an irrelevant feature. For the items that did not comply with the rule, the differed feature was a value of the rule for the high-similarity items, and a value of the rule plus two irrelevant values for low-similarity items.

Apparatus

The experiment was controlled by the ERTS software run on a PC computer. The pictures were presented as black line drawings on a white background on a (640x480) VGA monitor. Participants used a two-key response pad attached to the ERTS EXKEY-logic connected to the computer to express their response. One of the key was labelled YES and the other was labelled NO. Participants used their dominant hand to press the YES key. Participants' key responses and time elapsed from the presentation of an item to the participants' response were recorded.

Procedure

Participants were tested individually. They were seated in a quiet booth at a comfortable viewing distance in front of a monitor. They received the instructions displayed on the monitor. The instructions told them that they would see a series of pictures of abstract objects. Some of the pictures corresponded to 'good objects' and some to 'bad objects'. Participants' task consisted of pressing the key labelled YES if the abstract object was a 'good object' and press the key labelled NO if the abstract object was a 'bad object'. Before the initiation of the experiment, participants were presented with 10 trials with either YES or NO displayed

on the screen to familiarise them with pressing the YES/NO keys. Participants were given a rule (see above) to determine whether an object was a good object or not. Immediately after the written description of the rule, participants received a graphic example of the rule.

The experimental session was divided into 5 blocks: there was 1 training block and 4 test blocks. During the training phase participants were given 36 trials made up of 12 training items seen 3 times each in a random order. Participants controlled the speed of presentation of each of the training items using the space bar.

After the training phase participants were given four blocks of test. Each test block consisted of 24 items selected randomly from the total of 96 test items, with the only constraint that each test block contained 12 items that comply with the rule (6 high-similarity items and 6 low-similarity items) and 12 items that broke the rule (6 high-similarity do non-compliant items and 6 low-similarity non-compliant items). The test items of each block were presented in a different random order to each participant.

After each of test block participants were reminded of the rule and were shown the 12 items from the training phase (this time they saw each training item only once). This was done with the aim to reinforce rule application. As during the training phase, this repeated training phase was controlled by the participants using the space bar. Participants were asked to respond as quickly as possible without compromising accuracy.

Results

We begin with the *error analysis*. In the case of the simple, 1 feature rule, 123 (2.84%) from a total of (96x45) 4320 responses were errors, that is the participant either pressed the YES key when the NO key was appropriate according to the rule or the other way round (see Table 1). For the complex, 3 feature rule, the data of 4 participants was not included because they failed to respond using the correct key for all the trials of at least one of the blocks in one of the conditions. From a total of (96x42) 4032 responses, 305 (7.56%) were errors were the participant pressed the YES key when the NO key was expected or the other way round (see Table 1).

Table 1: Errors for both 1 and 3 feature rules. "C" indicates items which comply with the rule, "N" items which violate it, "High"- and "Low" refer to the degree of similarity to the test items.

	C-High	C-Low	N-High	N-Low
Errors 1	26	33	36	36
Errors 3	46	61	92	107

We begin with the analysis of the simple, 1 feature rule. Though there were slightly more errors on the low similarity items which complied with the single rule, as we had expected, a paired t-test comparing the proportion of errors made by each subject in across high vs. low similarity comply did not reach significance ($t(44) = 1.26$, $p = 0.1$, one-tailed). The expectation that on the non-rule compliant items there should be more errors on the high similarity

items than on the low similarity non-compliant items was not born out at all, with equal numbers of errors in both cases. In summary, the error analysis for the simple rule revealed no effects of similarity on rule application.

A different picture is presented by the error data for the complex, 3 feature rule. Again, there were more errors on the low-similarity compliant items than on the high-similarity compliant items as expected, but here the difference is statistically significant ($t(41) = 2.10$, $p < 0.02$, one-tailed). Again, the expectation that, of the non-compliant items, it should be the high similarity ones which elicit more errors was not born out in that participants made more errors on the low similarity, non-compliant items (Table 1); however, this unexpected difference, tested post hoc, was not significant ($t(41) = 1.48$, $p = 0.115$, two-tailed). In summary, at least for those items which comply with the rule, a significant effect of similarity on rule application emerged.

Finally, a comparison of the error proportions for the simple and complex rule revealed the expected higher level of errors in the complex rule condition: two 2-way Analysis of Variance (ANOVA) (one for the compliant items and another for the non-compliant items) with similarity (High vs. Low) within subject and rule (simple vs. complex) between subject analysis showed a main effect of rule complexity for the non-compliant data ($F(1,85) = 18.56$, $p < 0.0001$) but not for the compliant data ($F(1,85) = 2.21$).

In summary, the analysis of the error data revealed similarity effects for the complex rule, but not the simple rule. We next ask whether this finding is confirmed by participants' reaction times.

Reaction Time Analysis. We begin with the simple, 1 feature rule condition. For each participant we calculated the mean reaction time of response for each condition per block, giving us 16 data points per participant. These data point were transformed into their logarithm. This formed the bases for our analyses. Table 2 shows the mean reaction time per condition and block across all participants.

Table 2: mean reaction time across participants for one-feature rule.

	C-High	C-Low	N-High	N-Low
Block 1	565	587	662	626
Block 2	541	540	548	521
Block 3	514	515	530	583
Block 4	534	513	551	528

We analyse the compliant and the non-compliant items separately, not only because we expect different patterns of result, but because two different hands were used for YES and NO responses and therefore the RT's from the dominant hand are not directly comparable to those of the non-dominant hand.

A two-way ANOVA (fully within) was performed on the reaction time data for the *compliant* items. The variables were block (1-4) and similarity (high vs. low). A main effect of block was found ($F(3,132) = 7.15$, $p < 0.0001$). No main effect of similarity was found ($F(1,44) = .083$) and there was no interaction ($F(3,132) = .102$).

A further two-way ANOVA (fully within) was performed on the reaction time data for the *non-compliant* items. Again a main effect of block was found ($F(3,132) = 29.32, p < 0.0001$). No main effect of similarity was found ($F(1,44) = .804$) but the interaction was significant ($F(3,132) = 8.92, p < 0.0001$).

Repeating these analyses for the complex rule condition, we calculated, for each participant, the mean reaction time of response for each condition per block, giving us 16 data points per participant. These data points were transformed into their logarithm to minimise individual differences. This formed the bases for our analyses. Table 3 shows the mean reaction time per condition and block across all participants.

Table 3: Mean reaction time across participants for complex-rule condition.

	C-High	C-Low	N-High	N-Low
Block 1	1166	1276	1056	1166
Block 2	1018	1077	815	837
Block 3	934	976	723	736
Block 4	902	939	732	780

A two-way ANOVA (fully within) was performed on the reaction time data for the *comply* condition. The variables were block (1-4) and similarity (high vs. low). A main effect of block ($F(3,123) = 13.67, p < 0.0001$) and of similarity ($F(1,41) = 18.42, p < 0.0001$) was found. However, the interaction did not reach significance ($F(3,123) = 1.58$).

A further two-way ANOVA (fully within) was performed on the reaction time data for the *non-compliant* items. Again a main effect of block ($F(3,123) = 69.69, p < 0.0001$) and of similarity ($F(1,41) = 12.78, p < 0.001$) was found. However, the interaction did not reach significance ($F(3,123) = 1.72$).

Finally, comparing the simple and the complex rule condition, participants were significantly faster classifying on the basis of the simple rule, as predicted for both the compliant condition ($F(1,85) = 173.93, p < 0.0001$) and the non-compliant condition ($F(1,85) = 121.80, p < 0.0001$).

We illustrate the implications of the above analyses of reaction times with reference to two graphs plotting the mean reaction times for both kinds of rules, and high and low similarity items, with one graph each for the compliant (Figure 2) and the non-compliant items (Figure 3).

The main interest of the experiment, lies in potential differences between high- and low-similarity items, both as a function of rule complexity and of the amount of training.

As can be seen from Figure 2, the difference in reaction time for high and low similarity items is much greater for the complex rule than it is for the simple rule.

The difference also does not seem to change much with practice. These informal observations are confirmed in the above analyses in that there is no consistent effect of similarity in the case of the simple rule (the ANOVA found no main effect of similarity, nor any interaction between similarity and block) while there is an effect of similarity for the complex rule. However, this effect does not change significantly with practice, that is across blocks (the

ANOVA showed a main effect of similarity, but no interaction).

Figure 2: Plotted along the x-axis is the number of blocks, plotted along the y-axis is the mean reaction time. R-1 refers to the simple rule, R-3 to the complex, and H and L stand for high and low similarity to training items.

The non-compliant items deviate from this picture only slightly. As can be seen from Figure 3, the magnitude of the difference between high- and low-similarity is again greater for the complex rule, which also shows no clear effect of practice. This is confirmed by the above statistical analysis: for the non-compliant items in the complex rule condition there is, once again, a significant main effect of similarity, but no interaction between similarity and block. The data for the non-compliant items of the simple rule are not quite as clean showing an anomalous increase on block three. As a result of this increase, there is a significant interaction between similarity and block, but as before with the compliant items, there is no main effect of similarity. Crucially, the failure to show a consistent similarity effect observed in the compliant items is thus replicated in the non-compliant items.

Figure 3: Plotted along the x-axis is the number of blocks, plotted along the y-axis is the mean reaction time. R-1 refers to the simple rule, R-3 to the complex, and H and L stand for high and low similarity to training items.

In summary, then, we find similarity effects only for the complex rule, not the simple rule – a result which corresponds with the findings from the error analysis. Furthermore, there is no evidence that this similarity effect goes away with increased practice.

Discussion

The most important result of this experiment is that it manages to replicate the previously observed intrusion of similarity on rule-application even though there was nothing about the rules themselves which in any way made similarity seem relevant.

The similarity effect was apparent both in the error patterns and in participants reaction times and the finding that the similarity effects (where present) did not seem to abate with increased practice in applying the rule further underscore the generality of the observed interplay between rule-application and similarity assessment.

However, we failed to find a consistent effect of similarity in the simple rule condition. One must be cautious in interpreting such a null-effect in a single study in that an effect might well be observable given slight changes in experimental procedure or a considerably larger sample. However, the failure to find an effect does suggest that the role of similarity is not independent of rule-complexity and in that sense neither ubiquitous nor completely automatic. In contrast, the similarity effect found on the complex rule is very robust.

Why might one find effects of similarity in the context of rule application at all, and can our differential results for rules of different complexity be linked into an explanation? The weakness of rule-based reasoning lies in the fact that it is so exceedingly difficult to come up with perfectly predictive rules. Most regularities seem to be prone to countless exceptions, or hold only relative to certain background assumptions which are virtually impossible to capture. For example, the rule "birds fly" is true by and large, but there are some birds which don't. Making rules more specific doesn't eliminate the problem: "robins fly" seems true enough, but, again, will be false if the robin in question has broken its wing, has its feet stuck in concrete, or has eaten too many worms... The potential exceptions are endless and there seems to be no clean cut way of ruling them out in advance. These difficulties have dogged rule-based approaches within Artificial Intelligence which were once held to lead to "expert behaviour" within decades. The frame problem, the difficulties encountered by the naïve physics project (Hayes, 1979), and the difficulties in formalising defeasible inference (e.g., Reiter, 1980) are testimony to these difficulties (see also Pickering & Chater, 1995, for discussion).

Our assumption is that similarity might go some way toward alleviating these difficulties, thus allowing human beings to harness the undoubted power and clarity provided by explicit rules. Specifically, tracking the similarity of a potential candidate instance of the rule to previously encountered instances may provide a means whereby one is alerted to potentially deviating circumstances, where the rule – though seemingly applicable – does not, in fact apply. The fact that a novel instance seems dissimilar from previous instances might be a clue to the fact that it should actually be treated differently. This, we would argue, is one of the reasons why an interplay between rules and similarity seems profitable, and hence, is pervasive in large scale legal systems such as the law (see Hahn & Chater 1998a and 1998b for fuller discussion). If this is true, tracking

similarity in the context of rule application would seem useful in most contexts, but we might expect greater reliance on similarity under conditions of increased uncertainty. One way of looking at the increase in rule complexity is as an increase – for participants – in uncertainty. This also seems compatible with Nosofsky, Clark and Shin's (1991) observation of similarity effects despite an explicit rule as their task required fine-grained perceptual distinctions along continuous valued dimensions, which it seems unlikely could be achieved exclusively by the rule. However, further experimentation is required to establish whether the uncertainty reduction is indeed central. The most obvious experimental path to pursue is that of increasing uncertainty in the case of the simple rule, for example by introducing exceptions, thus making the classification task "noisy", or by making the differences in appearance even more extreme. In the meantime, what our results suggest is that instance similarity has some role to play in rule application – a role which needs both further clarification and a satisfactory explanation.

Abstract

Sometimes humans have a need for storing long sequences of information in memory. Several experiments show that grouping the items in the sequence helps storing the sequence in auditory short-term memory. One architecture used by connectionist cognitive researchers when representing and processing sequences is Recursive Auto-Associative Memory. One of the aspects of it is that its capacity for storing sequences is limited, leading to that the longer the sequence the less likely it is that the entire sequence can be recalled; the deepest parts of the sequence are forgotten. Two experiments are performed to test if grouping affects storage in Recursive Auto-Associative Memories. We conclude that grouping affects the ability for storing sequences in Recursive Auto-Associative Memories much in the same way as it affects the human auditory short-term memory, i.e., using grouping increase the probability of that the sequence can be recalled correctly.

Introduction

One technique for studying how memory is constructed is serial recall (see for example Baddeley, 1999 and Bridges and Jones, 1996; Pickering, Gathercole, Hall and Lloyd, 2001). A sequence of items (for example objects, digits, letters, etc.) is presented to the research subjects. The task for the subjects is to recall all items in the sequence in the same order as they were presented.

One of the aspects studied using serial recall tasks is how to increase the ability of the subjects to recall longer sequences.

Martin and Fernberger (1929) performed such a study regarding the improvement of auditory short-term memory. They concluded that the ability to remember sequences increased, if the objects in the sequence were organized in groups. Wickelgren (1964) and Pollack, Johnson and Knaff (1959) among others later confirmed this.

Grouping entails that the sequence is divided into shorter sub-sequences. The actual grouping has in previous experiments been done in two ways. Either the size of the groups is decided by the experiment leader (cf. Wickelgren (1964); Pollack, Johnson and Knaff (1959)) or the size of the groups is selected by the subjects and can vary within a sequence (cf. Martin and Fernberger (1929); Baumann and Trouvain (2001)).

Inspired by the findings of Martin and Fernberger (1929); Pollack, Johnson and Knaff (1959) and Wickelgren (1964), that grouping can increase the ability to recall longer sequences, the interest here is to test how grouping affect the recall of sequences in Pollack's (1990) Recursive Auto-Associative Networks (RAAMs). A RAAM is a type of artificial neural network used for representing sequences and structures of unknown or dynamical size. It has previously been used in experiments involving manipulation of structured objects (e.g. sentence transformation (Chalmers, 1990), language translation (Chrisman, 1991)). These experiments showed that RAAM uses the sequential order of the presented objects to develop highly structured (spatial) internal representations. In the experiments presented in the following a variant of these networks, called Extended Recursive Auto-associative Networks (ERAAM), originally suggested by Niklasson and Sharkey (1992), will be used.

Grouping experiments

The exact definition of what a *group* is varies. According to Wickelgren (1964), Fraise (1945) defined a *group* as a cluster of correct items separated by one or more errors. Wickelgren noted that this way of defining groups assumes that the items in a group are rarely forgotten and that the subjects practically never can remember two groups in succession. Others, for example Baumann and Trouvain (2001), used rhythm of speech and intonations for finding groups when the subjects recalled the sequences. Wickelgren defined a *grouping method* as a method for *rehearsal*, i.e. grouping in twos means rehearsing the items in twos; grouping in threes means rehearsing the items in threes; etc.

A large number experiments on how grouping affects the ability to recall longer sequences have been conducted. Most of these experiments confirm each other in that they show similar results.

Martin and Fernberger (1929) trained subjects to remember long sequences. This was achieved by the subjects using increasingly larger groups (first the subjects used groups of size two, after a while groups of size three and so on). Martin and Fernberger noted that the performance increased up to groups of size 5, after that the performance decreased.

Pollack, Johnson and Knaff (1959) confirmed these results using temporal grouping (i.e. making a short pause between the groups when presenting the sequence for the subjects) for items presented in 1's, 2's, 3's, 4's and 6's. According to their experiment, using groups of size four resulted in the best overall performance. Note however, that they did not test groups of size five, which Martin and Fernberger (1929) concluded was better than other group sizes.

Wickelgren (1964) also conducted experiments on how different groupings affected recall. According to that study groupings in threes were the best, closely followed by grouping in fours. The worst was grouping in twos, closely followed by grouping in fives. Groups of one item resulted in a performance quite close to the five-grouping, see figure 1.

Figure 1: Results from Wickelgren's (1964) experiments for grouping in human short-term memory. Error rate is used to measure the subjects' performance.

In his experiments, Wickelgren used *error rate* to compare performance using different groupings. The error rate for a group is calculated by dividing the number of incorrectly recalled sequences (all items must be recalled in the correct order for the sequence to be regarded as correctly recalled) with the total number of sequences.

ERAAM

As its name suggests, the Extended Recursive Auto-Associative Memory (ERAAM), originally suggested by Niklasson and Sharkey (1992), is an extension of Pollack's (1990) Recursive Auto-Associative Memory (RAAM), which is a connectionist architecture able to represent dynamically large structures (for example sequences) in a fixed-sized artificial neural network. Due to several of its features it has been used by several cognitive researchers who want to investigate theories for sequence recall (see for example Adamson and Damper (1999); Blank, Meeden and Marshall (1992)). One of the features is that the network is trainable, i.e. that it can learn to represent, for example, a specific type of sequence. Another feature is that RAAM during recall is more likely to produce decoding errors the more complex the sequence is. The errors usually appear towards the end of the sequence, quite like humans (cf. Henson (1996), Baddeley, (1999) and Adamson and Damper (1999)).

Figure 2: The structure of ERAAM. The extra bit in the input and output layers is used to classify if the representation is a terminal or a composite structure. *d1* is the compressed representation of *a* and *b*. *d2* is the compressed representation of *c* and *d1*. Due to decompressing errors we do not get *exactly* the same representation as we put in. To illustrate this, *a'* and *b'* are the representations from the decompressed *d1* and *c'* and *d1'* results from the decompressed *d2*. Note that the RAAM requires fixed valence on the structures represented.

In RAAMs two networks are involved: a compressor and a decompressor. The compressor consists of an input layer where an item in the sequence is presented together with a compressed representation of the previously presented items of the sequence and an output layer that contains the compressed representation of new item in combination with the previous (in figure 2 '*d1*' is a compressed representation of the combination of the terminals '*a*' and '*b*' and '*d2*' is a compressed representation of the terminal '*c*' and the non-terminal (i.e. previously compressed) '*d1*'). The decompressor consists of an input layer containing the compressed representation and an output layer containing the (partially) decompressed representation. The compressor and decompressor networks respectively are used recursively to do further compressions or decompressions of sequences.

When decompressing, a terminal test is normally performed on the decompressed representations to see if any of them is a terminal and therefore should not be further decompressed. The terminals contain the representation of the items in the sequence. Different alternative methods for this terminal test have been proposed (see for example Chalmers (1990); Pollack (1990)). ERAAM is another suggestion for how to interpret if a decoded representation is a terminal or non-terminal. In ERAAM an extra bit of information has been added to each part of the sequence. If the representation is a terminal this bit is set to 1 and otherwise 0, see figure 2. This extra bit is compressed and decompressed along with the other information. When, during decoding, a 1 is encountered as the last bit in the representation, this is interpreted as the representation being a terminal. The representation is then compared to the representations for the known terminals and the terminal that is closest in Euclidean space is the one said to be present in the output.

Experiment 1

The purpose of this experiment is to see how grouping affect the ability to recall longer sequences in ERAAMs. In the experiments Wickelgren's (1964) definition of grouping as a method for rehearsal is used, i.e. the ERAAMs rehearse the groups in the sequence as well as the complete sequence. The group sizes vary from 1 to 6, but the same group size is used throughout the sequence. According to Baddeley (1999) grouping can be used as long as the subjects can notice the presence of the groups. In order to mark the boundaries of groups a 'nil' character is used marking the beginning of a new group.

Method

Sequences The sequences are entirely made up by digits between 0 and 9 and 'nil' representing spacing between groups. The digits and the 'nil' character have orthogonal representations so as not to give any benefit of grouping several representationally similar digits together. The sequences used are produced by picking a random digit for each position in the sequence. However, extra constraints are used. Each digit may only appear once during the first ten positions in the sequence, only once between the eleventh and twentieth position and only once between the twenty-first and thirtieth position, this to prevent that the probability for a specific digit to appear is larger than for the others thereby making the sequence a bit easier to learn. Furthermore, for groups of size two a specific digit may not occur in the same position *within* a group twice for the first twenty positions in the sequence. For groups of size three no digit may appear in the same position in a group during the first thirty items, and so on. This is done to ensure that the probability for a group to contain a specific digit in a specific position should be similar to the probability of other digits thereby giving as little advantage as possible to any digit combination in a group and as little advantage as possible to any specific group size.

Three sequences are generated following the above constraints:

- 97250831645982164073516,
- 58472096133509847261915,
- 25713680491368049257804

From each of these sequences twelve subsequences of are created varying in lengths from 12 to 23 digits. The subsequences of length 12 are constructed from the twelve first digits in the above sequences, the subsequences of length 13 are constructed from the thirteenth first digits and so on.

In order to separate the groups that the subsequences are divided into a 'nil' character was inserted marking the beginning of each group. This is done after the groups are constructed (see figure 3).

Figure 3: example of how the sequences are organized. To the left an ungrouped sequence, to the right a sequence with group size of four. Nil is used as an end marker.

ERAAMs 30 Extended Recursive Auto-associative memories are used having 2×11 sigmoidal input and output nodes and 10 sigmoidal hidden nodes. Each ERAAM has a unique and random initialization so as to minimize the probability that the experiments, by coincidence, give bias to some specific group size.

Procedure Each subsequence is trained on all the thirty ERAAM networks. Each network is trained using backpropagation on the given subsequence for 200,000 iterations. This number of iterations is established by several dry runs, where almost no changes in the learning of the network are detected after 50,000 iterations and no changes are detected after 150,000 iterations. The limit is set to 200,000 iterations to give the ERAAMs plenty of time to learn the subsequences, but still provide an upper limit to the training time.

The ERAAMs receive the subsequence one item at a time, but each group in the subsequence is trained to be reproduced separately.

The ERAAMs are tested after 200,000 iterations on whether or not they can compress and decompress the entire subsequence they have been training on.

The ERAAM is considered successful in this experiment if the entire recalled subsequence is compressed and decompressed correctly, i.e. there must not be a single error anywhere in the decompressed subsequence.

Results and Discussion

The proportion of errors in relation to number of trials in each group (i.e. the same measure as used by Wickelgren, 1964) can be seen in figure 4. For group size 1 the proportion of errors for sequences of length 12 to 23 is .748. For groups of size 2 it is .820. For groups of size 3 it is .768. For size 4 it is .745. For size 5 it is .729 and finally for groups of size 6 it is .769. It seems as if, analogous to Wickelgren's (1964) results, using a group size of 2 yields the worst result. We can also see that when using larger groups the error rate decreases until the use of group size 6. However, the performance is never much better than that achieved using an ungrouped sequence.

In the experiments the performance declines in a sigmoidal fashion from almost correct recall of ungrouped sequences of length 12 to none correctly recalled at sequence lengths of 20 or more.

The results acquired indicate that grouping *has* an effect on the ability to recall sequences in ERAAMs. It is better to

group a sequence into fours and fives than into twos with respect to the probability of recalling the sequence correctly. However, the ungrouped sequence is about as likely to be recalled correctly as using groups of size four and five. There are two possible reasons for this.

Figure 4: summary of results for experiment 1. As we can see, in almost 75% of the trials the ERAAMs fail to correctly encode and decode the entire sequence. We can also see that grouping for the most sizes makes this worse. However when using groups of sizes four and five there are fewer errors made than in the ungrouped sequences.

The first one is that grouping has no advantage in sequence recall compared to the ungrouped case.

The other reason is that in the grouped sequences there are extra characters inserted: the 'nil' characters. Since they are items as well as the digits this has the effect that the sequences get longer; more items need to be correctly recalled in the grouped sequences than in the ungrouped. This makes the task harder. If this is indeed the case, then it can be noted that the recall of sequences divided into groups of size four and five have the same performance as the ungrouped sequence, actually indicating that grouping has influence. To test whether this is the case, another experiment was performed where the 'nil' characters was removed.

Experiment 2

Whereas the performance in experiment 1 never gets much better for a grouped sequence than for an ungrouped sequence, an interesting effect can be seen in that the use of group size 2 is the worst, but, as the size of the groups increase, the error rate decreases leaving at the group size of 5 a result about the same as an ungrouped sequence before getting worse again with groups of size 6. What differs between the grouped sequences, other than the group size, is the number of 'nil's used, being the most in groups of size two and then gradually decreasing with larger group sizes. Since 'nil' is an extra character, in practice, the sequence gets as much longer as the number of groups used than if it had been ungrouped.

To test whether or not the 'nil' character, since it makes the sequences longer, makes it more difficult for the ERAAMs to learn the sequences another round of

experiments are performed, this time without the 'nil' marking the boundaries of the groups.

Method

Sequences The same subsequences as the ones used in experiment 1 are also used here. The difference between the subsequences in this experiment and the previous is the grouping method. In this experiment 'nil's are not used to mark group boundaries, see figure 5. This leads to that the subsequences contain the same number of items regardless of the group size used, whereas in the previous experiment the 'nil's constitute extra items making the subsequences longer.

Figure 5: example of how the sequences are organized. To the left an ungrouped sequence, to the right a sequence with group size of four.

As in experiment 1 the size of the subsequences varies between 12 and 23.

ERAAMs The same ERAAMs as in experiment 1 are used; 30 differently initialized ERAAMs of size 2*11 sigmoidal input and output nodes and 10 sigmoidal hidden nodes.

Procedure As in experiment 1 the ERAAMs are trained to compress and decompress the given sequence for 200,000 iterations using backpropagation. The ERAAMs are reset to their initial configuration between each sequence so that the training of one subsequence does not affect the next.

After training, the ERAAM is tested whether or not it can compress and decompress the entire subsequence. As before, the entire subsequence must be correctly reproduced for successful result, otherwise the ERAAM is considered to have failed in representing the subsequence.

Results and Discussion

The error rates for different groupings can be seen in figure 6. For groups of size 1 the overall error rate (the number of correctly compressed and decompressed sequences divided by the total number of sequences used) is .577, for size 2 it is .482, for size 3 it is .402, for size 4 it is .358, for size 5 it is .398 and for groups of size 6 it is .370. It seems as if grouping the sequence leads to better performance, continuously improving until group size 4 when the performance cease to improve any further, see figure 6.

There is now a clear benefit shown of using grouping when trying to recall longer sequences. Using the group size of four yields a 41% better result (the difference between the number of incorrectly recalled sequences for an ungrouped sequence and the number of incorrectly recalled sequences using group size four divided by the number of

incorrect ungrouped sequences) than trying to represent an ungrouped sequence.

Figure 6: summary of results experiment 2. As we can see, not grouping the sequence here leads to that fewer sequences are recalled than in the grouped cases. We see that using groups of sizes four, five and six results in that more sequences are correctly recalled.

We can also see that this way of grouping the sequences results in that more sequences are correctly recalled than when using 'nil's as group separators.

General Discussion

Sometimes there is a need to store dynamically long sequences in a memory. One of the techniques used by connectionist cognitive researchers, is to compress the sequences using recursive auto-associative memories (RAAMs). However, as in human memory, an aspect of the RAAM architecture is that the longer the stored sequence is the more probable it is that the deepest parts of the sequences cannot be recalled correctly, due to some compressing and decompressing errors. Since grouping a sequence increases the probability that it is correctly recalled in human memory we set out to test if grouping has a similar effect when recalling sequences in Extended Recursive Auto-Associative Memories (ERAAMs).

The experiments reported here show that grouping has a large impact on the probability that the sequences are correctly recalled. The probability that a sequence between the size of 12 and 23 is recalled correctly is on average 41% better using the group size of four instead of not using grouping at all.

The problem when recalling long sequences is that the deeper into the sequence, the more likely it is to miss-recall an item due to cumulating compressing and decompressing errors. We believe that grouping, dividing the sequence into smaller sub-sequences that are linked, works since it decreases the depth that needs to be recalled. The larger the groups the more the depth is decreased. After a while, however, the sub-sequences get so large that they also start to suffer from errors. This means that, as in humans, using increasingly large groupings the performance starts to decrease again.

In many situations there is a need to store long sequences. It is well known that grouping the sequence makes it easier to recall in auditory short-term memory. We see that this is also true for ERAAMs; grouping the sequences that are to be stored leads to an increased probability that they are correctly recalled.

What is suggested here is that RAAM like architectures can be used to model the human ability to store and recall sequences. However, many questions demand answers before networks of this kind can be said to model all the aspects of human memory. This includes questions concerning biological plausibility, a performance more closely matching the human, especially when using meaningful subsequences, etc. The results presented here show that RAAM like architectures indeed have a promising potential for supplying the answers to these questions.

Holographic Reduced Representations for Oscillator Recall: A Model of Phonological Production

Harlan D. Harris (hharris@uiuc.edu)

University of Illinois at Urbana-Champaign

Department of Computer Science, MC-258

Urbana, IL 61801

Abstract

This paper describes a new computational model of phonological production, Holographic Reduced Representations for Oscillator Recall, or HORROR. HORROR's architecture accounts for phonological speech error patterns by combining the hierarchical oscillating context signal of the OSCAR serial-order model (Vousden, Brown, and Harley 2000; Brown, Preece, and Hulme 2000) with a holographic associative memory (Plate 1995). The resulting model is novel in a number of ways. Most importantly, all of the noise needed to generate errors is intrinsic to the system, instead of being generated by an external process. The model features fully-distributed hierarchical phoneme representations and a single distributed associative memory. Using fewer parameters and a more parsimonious design than OSCAR, HORROR accounts for error type proportions, the syllable-position constraint, and other constraints seen in the human speech error data.

Introduction

The phonological production subsystem is the part of the language production apparatus that sequences the sounds in individual words and groups of words. Phonological production is the mapping from lexical units, morphemes and words, to sequences of phonological units, phonemes. This paper presents a new model of the phonological production system, a model that offers a new explanation for errors and serial order in speech.

Speech Error Effects

Numerous constraints and patterns have been observed in speech error patterns, including error type proportions (see Table 1), the syllable position constraint, the C-V category constraint, the distance constraint, the phonological similarity effect, and the phonotactic regularity effect (Fromkin 1971). Unless otherwise specified, the numbers in the descriptions below are from the (Vousden et al. 2000) analysis of the (Harley and MacAndrew 1995) error corpus.

A strong constraint on movement errors (the first three error types in Table 1) is the *syllable position constraint*, or SPC. 89.5% of movement errors retain their position in the syllable (onsets move to onsets, vowels to vowels, etc.).

Type	Rate	Example
anticipations	35.1%	det the dog
perseverations	26.0%	pet the pog
exchanges	10.6%	det the pog
non-contextual slips	17.3%	pet the log
mixed errors	11.0%	let the pog

Table 1: Error type proportions. Target utterance is "pet the dog." Mixed errors include any error not in the other categories.

An even stronger constraint is the *consonant-vowel category constraint*, or C-V constraint. Errors very rarely involve the replacement of a consonant by a vowel or vice versa. A superset of these errors, those that violate language-specific rules (the *phonotactic regularity effect*), occur in less than 1% of errors (Stemberger 1983).

The *distance constraint* is the observation that phonemes tend to move only short distances (one or two syllables) in movement errors.

When movement errors occur, they are more likely than chance to involve phonemes that share phonetic features. For example, "pig bull" for the intended "big pull" is a more likely exchange than "bill pug," since [p] and [b] are more similar than are [g] and [l]. This is the *phonological similarity effect*.

Language Sequencing Models

Phonological production models can be categorized by how they generate serial order. I follow Vousden et al. (2000) and use the terms *associative chaining model*, *frame-based model*, and *control signal model*.

Associative chaining models account for serial order by having each subsequent phoneme be triggered by a combination of the pattern of previous phonemes and a representation of the target utterance (Dell, Juliano, and Govindjee 1993). These models successfully account for phonotactic regularity effects and the C-V constraint, but they do not generate anticipations and exchanges well, nor do they account for SPC effects.

Frame-based models (Dell 1986; Roelofs 1997) use strict phonological frames to slot phonemes into pre-

specified positions, such as the onset, nucleus, and coda positions of a syllable. These models often use chains of sequencing nodes to activate the slots sequentially (Eikmeyer and Schade 1991). Although frame-based models are influential, sequencing nodes are often criticized as being poorly motivated.

To address this point, control signal models (Burgess and Hitch 1992; Hartley and Houghton 1996; Vousden et al. 2000) replace discrete syllable frames with continuous time-varying signals. Prior to production, different parts of the word are associated with different parts of the signal. Then, as the signal changes during production, the associated phonemes are output sequentially. Simple control signal models explain how phonemes could be produced in order, but don't account for SPC effects.

The OSCAR model (Vousden et al. 2000), described below, is a complex control signal model that accounts for SPC effects by using a multi-dimensional control signal with biological motivation. It contains an implicit frame in the way that the control signal is structured, but does not require explicit slots or sequencing nodes for production.

Building Blocks

The HORROR model combines elements of two previously existing models: the OSCillator-based Associative Recall (OSCAR) model of serial-order and phonological production (Brown et al. 2000; Vousden et al. 2000), and the Holographic Reduced Representations (HRR) model of hierarchical associative memory (Plate 1995). Prior to describing HORROR, I review its two ancestral models.

OSCAR

OSCAR works by associating item vectors (phoneme representations) and phonological context vectors (PCVs) in a Hebbian associative memory. The PCVs are inspired by oscillating signals in the brain, and have an important hierarchical self-similarity pattern, described below. As the PCVs are iteratively presented to the associative memory, the original item vectors are recalled and become available for production. The self-similarity pattern generated by the oscillators, when combined with noise, generates patterns of errors that previously required the use of syllable frames.

In OSCAR, there are 30 oscillators in two groups of 15. In the non-repeating group, the oscillators generate sinusoidal values at frequencies ranging from very slow to very fast. Initial phases and frequencies are generated with sufficient randomness that the non-repeating group's state does not repeat for many steps. In the repeating group, the initial phases of the oscillators are random, but the frequencies are identical. The state of this group repeats precisely every three time steps, representing the period of a three-segment CVC syllable.

Figure 1: HORROR's PCV self-similarity function.

The PCV itself is generated by multiplying together selected oscillator signals to form a 32-element vector. Each element is a product of four oscillator signals, all of which are selected from the same group (repeating or non-repeating). The pattern of multiplications results in an automatically normalized PCV, allowing easy comparisons for similarity.

A key feature of OSCAR is that the PCV is self-similar in a hierarchical manner. Each state of the PCV is most similar to states that are multiples of three time-steps away, but nearby states are also somewhat similar (see Figure 1).

The process for producing a "word" (a randomly generated 18-segment sequence of six CVC syllables) is as follows. A PCV is initialized, and starts to change with time. At each time step, the PCV is associated with a phoneme feature vector in a Hebbian weight matrix. Each time step uses a *separate* weight matrix. This entire process is performed nine times (in parallel), to create a total of 81 weight matrices, nine replications of nine time steps. To produce the sequence, the PCV is re-instated to its initial state, then sequentially re-produces each step's state. The PCV is usually associated with the correct weight matrices to generate an approximation of the phoneme feature vector. In addition, a probabilistic process is used to generate errors. 70% of the time, segments which are associated with PCVs that are similar to the current PCV are combined with the output from the correct weight matrix. The result is an output vector, a potentially noisy approximation to the correct phoneme. Also, a post-output suppression mechanism is used to reduce excessive perseveration and facilitate exchange errors. The generated output vectors for each of the nine replications are compared to an item memory containing each phoneme, such that each phoneme is activated to an extent proportional to the similarity with the nine output vectors. The most active phoneme is then produced in a winner-take-all process.

OSCAR's Pros and Cons In many ways, OSCAR is important work in the literature of phonological production and speech error modeling, but it has significant problems that may limit its applicability. Its contributions include making good use of an independently-motivated context signal to create serial order, accounting for SPC effects without position-specific phonemes, and using an implicit rather than explicit syllable frame. Overall, it accounts for various error patterns better than do chaining models.

However, several limitations lead me to question the extent of the model's successes. Most importantly, the noise-addition procedure is unprincipled. As well, the artificial words did not include repeated phonemes, the associations between the context and phonemes are stored separately, and there are a concerning number of parameters.

Consider the noise-addition procedure. Cognitive models should use reasonable sources of noise to generate error phenomena. Many models add Gaussian noise, while others use intrinsic noise from distributed representations and imprecise network computation. Although OSCAR uses well-motivated oscillator signals to provide serial-order effects, its noise-generation procedures are much more weakly motivated. As described above and in Appendix C of Vousden et al. (2000), phonemes associated with states of the PCV that are selected by their similarity to the correct PCV are recalled in parallel and used to corrupt the winner-take-all process.

That this procedure generates impressive error results is not surprising. The noise in OSCAR is generated only by interference from particular phonemes in the current sequence, not by any sort of random numerical noise or other natural interference. OSCAR claims to explain why most errors are movement errors – in their model, it's because the generated noise is movement noise.

A related concern with OSCAR is that the associations between the PCV and phoneme vectors are stored separately. Although it is reasonable to use Hebbian learning to associate a PCV signal with phoneme representations, it is difficult to explain why each segment need be stored in entirely separate sets of weights. A more parsimonious solution would use a single set of weights and would treat the resulting noise as an asset, not a weakness.

HORROR adopts the oscillating PCV system from OSCAR, but replaces the movement-based noise-creation system with the noise inherent in an associative memory system with overlaid weights. It also uses a more parsimonious unified memory system, allows repeated phonemes within a sequence, and requires fewer free parameters¹.

¹In addition to the five listed in Table 7 of Vousden et al. (2000), there are these four: the ratio of correct-to-incorrect activation, 0.6; the number of redundant associations, 9; the similarity threshold for allowing a

$$\begin{array}{ll}

 \end{array}$$

Figure 2: Holographic Associative Memory. $\mathbf{a} - \mathbf{h}$ are item vectors; \mathbf{T}_i are memory vectors. $*$, $\#$, and $+$ symbolize circular convolution (encoding), correlation (decoding), and addition (composition).

Distributed Associative Memories

For several decades, mathematical psychologists have looked at distributed representations for models of memory (Murdock 1982; Eich 1982), and have accounted for many recognition and recall effects. Compared to localist connectionist models, where representations consist of features and micro-features, distributed representations use long quasi-random vectors. These vectors are generated and manipulated such that similarity between two representations is defined by the dot product or cosine. Distributed representations can be combined in various ways. Two symbols may be associated by operations such as convolution or the outer product, resulting in another large vector. Retrieval from memory vectors is performed by inverting the association operation, correlation. Distributed memories can store a number of associations at once, simply by adding the vectors together. As vectors are overlaid, the amount of noise increases. This intrinsic noise is part of the model, and resulting simulations can account for list-length and item-similarity effects.

A limitation in much of the work on distributed memories is that the operations that generate associations greatly expand the size of the vector, with the result that hierarchies of associations are impractical. HORROR utilizes one of several approaches that overcome this problem, the Holographic Reduced Representations (HRRs) of Plate (1995).

With HRRs, the representations and associations are always fixed-length vectors. A circular version of convolution is used to associate vectors. The resulting memory vectors are the same length as the input vectors, at the cost of increased noise. The greatest benefit is that hierarchies of associations can be easily generated and stored. See Figure 2 for simple examples and notation. An auto-associative item memory (a Hopfield network or a nearest-neighbor search through a list) is necessary to identify the result of each correlation.

phoneme to be added as noise, 0.5; and the similarity exponentiation factor in the item memory, 3.4.

HORROR

Holographic Reduced Representations for Oscillator Recall (HORROR) is a model of serial-order processing that combines the self-similar context vectors of OSCAR with the hierarchical representations and memory of HRRs. The result is a fully-distributed phonological production model that accounts for errors in the serial-order part of the system by using the intrinsic noise from the associative-memory part of the system.

OSCAR and HRRs fundamentally both represent similarity by distance between vector representations. In OSCAR, the extent to which pairs of context vectors which are near in time are also near in space determines retrieval accuracy and error patterns. With HRRs, capacity and noise levels are determined by the extent to which composed vectors are near (not orthogonal) to each other. In OSCAR these similarity metrics can be complex and hierarchical, determined by the oscillator patterns, and in HRRs, the similarity metrics can also be hierarchical, by the process of overlaying associations. In both models, item memories are used to clean up and to select a single item.

HORROR is a new model based on the general framework of OSCAR. It takes a variation of the PCV from OSCAR, and combines it with an HRR associative memory, replacing the simple associative memory used by OSCAR. In addition, the feature-vector phonological representations used in OSCAR are replaced with fully-distributed hierarchical representations in HORROR. A critical aspect of HORROR is that all of the phoneme-context pairs that make up a sequence are stored together in a single large vector, rather than in OSCAR's many separate weight matrices. The noise in this memory vector, combined with representational similarity and the PCV structure, provide sufficient opportunities for appropriately distributed error patterns to arise.

Experiments

A major goal of this work is to account for the same human speech error data as does OSCAR, using a simpler structure, more parsimonious procedures, and fewer parameters.

As with OSCAR, PCVs are generated sequentially and convolved with phoneme representations to form memory traces. Unlike OSCAR, these traces are summed to form a single vector representing the entire sequence. To produce the sequence, the vector is correlated with the PCVs in order, resulting in noisy versions of the phonemes. The phonemes are cleaned up in an item memory, and the results are analyzed for various types of errors.

The oscillators used to generate the PCV were the same as used by OSCAR. HORROR additionally includes a parameter, *nrep*, that specifies the proportion of repeating versus non-repeating oscil-

Param.	Value	Description
<i>nrep</i>	17	# of non-repeating oscillators
<i>vw</i>	2048	Representation vector width
<i>cc</i>	3	Repeating oscillator inv. freq.
<i>D</i>	4	Speech-rate (larger = slower)
<i>Inhib</i>	.121	Post-activation inhibition level
<i>InDec</i>	.5	Inhib. decay (lower = faster)
<i>ds</i>	3	Phoneme dis-similarity factor

Table 2: Free parameters in HORROR

lators. The procedure of generating the PCV from the oscillators in HORROR is very similar to the procedure used in OSCAR, but since HORROR's PCV is very wide (2048 elements), the process was repeated with different random initial phases and frequencies in order to fill up the vector, which was then normalized. See Table 2 for the list of PCV and other parameters used in the experiments described below.

Vousden et al. (2000) use an articulatory-feature representation of phonemes. Each phoneme is 17 elements long, with binary features representing place and manner of articulation, nasality, voicing, and vowel position and tenseness. We converted these localist features into distributed features for the fully-distributed representations used in HORROR.

Phonological representations were built in a fully-distributed manner by generating random Gaussian vectors (of width *vw*) for each feature, then summing the appropriate features together and normalizing. Each vector thus has an intrinsic similarity metric, defined by the number of shared features. In order to partially "drown out" the similarity between otherwise very-similar phonemes, additional random vectors (*ds*) were added to each phoneme vector.

Decoding consists of sequentially correlating each time-step of the PCV with the single stored memory vector. The result is a series of approximations to the target phonemes, corrupted by the noise intrinsic to a holographic memory. Each recalled vector is compared to an item memory containing possible phonemes. The phoneme that is most similar to the recalled vector is then produced.

The item memory has three features that help it best account for the error patterns. First, each item in the item memory has a persistent activation level, *a*. Activation is added to similarity to determine which phoneme is selected. At each step, each item's *a* is increased by the item's distance from the recalled vector, weighted by the *Inhib* parameter. Second, after a phoneme is selected, it is suppressed by setting *a* to be the negation of *Inhib*. Post-output suppression is a common feature of this type of model (Vousden et al. 2000; Dell 1986). Finally, at every time step, activation decays toward zero according to the decay constant *InDec*.

Figure 3: HORROR's error type proportions.

Experimental Results

2000 6-syllable "words" were generated, associated, and output. Errors were determined by an automatic categorization process. Error type proportions, SPC violations, distance constraint statistics, and phonetic similarity constraint statistics were counted.

Error proportions 1538 errors occurred during production of 36,000 segments, resulting in an overall error rate of 4.3%. Figure 3 shows the proportions of error types. The results compare fairly well with the human data reported in Vousden et al. (2000). Exchanges, however, were under-represented in the model, raising the question of whether HORROR's exchanges are true exchanges or merely the joint event of independent anticipations and perseverations. Other speech error models (Dell et al. 1993; Roelofs 1997) are unable to produce true exchanges, and are therefore seen as incomplete.

To address this, I calculated the expected number of exchanges, assuming that they are coincidental. This number, 0.33 per 2000 sequences, was more than sixty times smaller than the number of exchanges actually observed (22), demonstrating a true tendency for exchanges. Exchanges in HORROR occur because post-activation inhibition helps to prevent an erroneously anticipated phoneme from then appearing in its correct location. Instead, the earlier, replaced phoneme may be triggered via the PCV, turning an anticipation into an exchange.

Distance constraint The model's movement gradients parallel the distance constraints seen in human data, with disproportionately small separations. Exchange errors shifted least, an average 0.95 syllables, followed by anticipations, averaging 1.4 syllables, and perseverations, averaging 2.9 syllables. Figure 4 shows a comparison on anticipations between HORROR and human data. The shorter movements made by exchanges, compared

Figure 4: Distance gradients of the anticipation errors produced by HORROR, compared with the human data and chance baseline of Vousden et al. (2000). Adjacent syllables have a distance of 1. Same-syllable errors (separation 0) are not shown.

Error type	n	Mean shared features
Movements	895	2.4
Exchanges	22	3.1
Non-contextual	306	3.1
Chance		1.9

Table 3: Average similarity for consonant errors. Movements are anticipations and perseverations.

to other error types, has been observed in human error data (Nooteboom 1973).

Phonetic similarity constraint Vousden et al. (2000) concentrate their analysis of the phonetic similarity constraint on consonant exchanges. HORROR produced only 22 consonant exchanges, 20 of which shared 75% or more of their phonetic features. Table 3 compares the categories of consonant errors to chance. Chance was determined by randomly selecting 1000 pairs of consonants, and counting the number of shared phonemes for each pair. The phonetic similarity constraint is clearly present in these results. Note that exchange errors were significantly more similar than were other movement errors. This is true for human exchanges, and also lends further support to the observed exchanges being real.

Syllable-position constraint 29.0% of the model's errors violated the SPC, compared to 10.5% of errors in human data (Vousden et al. 2000). To confirm that this number still reflects a constraint, and is not just the chance rate of violations, it's necessary to look at the probabilities of errors being in each syllable position. In this set of data, 50.7% of errors were in the onset, 8.6% in the vowel, and 40.8% in the coda. To

calculate the expected rate of SPC violations, assume that the consonant-vowel constraint is never violated, and that consonant errors have a 50% chance of movement from onsets and codas. Therefore, the expected SPC violation rate is $1 - (.086 + .507 * .5 + .408 * .5) = 45.7\%$. Although the SPC is violated more often by the model than it is in human data, it is still a real effect.

Consonant-vowel constraint Only 2.3% of the errors violated the C-V constraint, showing that the model is generally respecting the consonant-vowel categorical distinction seen in natural errors.

Repeated phonemes In order to investigate the role of repeated phonemes in the model, the same experiment was re-run with repeated phonemes disabled. Since repeated items are known to strongly affect performance in distributed memories, it was expected that the effects on HORROR would be significant as well. The error rate without repeated items was reduced to 1.3%, and the proportion of non-contextual errors was greatly reduced (see Figure 3). HORROR is more error prone when repetitions occur, as in human data (Dell 1986). Repeated phonemes appear to be an important trigger for speech errors, including non-contextual errors.

Discussion

The HORROR model combines the best features of OSCAR, a serial-order phonological model with a hierarchical context signal, and HRRs, a holographic associative memory using hierarchical representations. Its aim is to account for speech error patterns using more parsimonious mechanisms than previous related models.

HORROR succeeds in a number of ways. It allows repeated phonemes in the sequences, it combines associative memory traces into a single distributed association vector, and its error mechanism relies entirely on the intrinsic noise from the associative memory with no generated noise at all. It uses fewer parameters than does OSCAR, and accounts for a number of error patterns in human data. Specifically, the model's error type proportions, distance constraint, phonological similarity constraint, and C-V category constraint results were largely similar to human data. The SPC results were real, if modeled less accurately. HORROR accounts for these major speech error patterns by using fully-distributed hierarchical representations, a single intrinsically-noisy associative memory, and an oscillating phonological context signal.

Abstract

It has recently been suggested that knowledge is represented in the form of perceptual symbol systems (Barsalou, 1999). According to this view, perceptual states may be used to support higher cognitive processes without being transduced into a representational language. Since the ability to recognize difference and similarity is fundamental for cognition, we examined to what extent it might be based on perceptual information. In three experiments, participants made judgments of similarity and difference for simple items under three presentation conditions: Words Only, Words and Pictures, and Pictures Only. Reaction times for judgments in the Words-Only condition were consistently slower than in the other presentation conditions. However, judgments of perceived similarity and perceived difference did not markedly differ between presentation conditions. The results suggest that participants recruited perceptual information when evaluating similarity in the Word-Only condition. Additionally, presentation condition had an effect on the relation between the similarity and difference scales: for a given degree of similarity, more extreme difference judgments were found under those conditions where words were displayed. We offer an explanation for this effect, and present a further research program.

Introduction

Similarity, or psychological resemblance of entities, is a fundamental aspect of cognition. Similarity plays a critical role in perception, memory, learning and transfer, categorization, analogical reasoning, problem solving, and language comprehension. It has also been suggested that recognizing differences between entities is fundamental to cognition; for instance, in discriminating category members from non-members. An extensive body of research then has outlined the processes for which similarity and difference are important. However, much less is known about that nature of the information recruited for evaluating similarity and difference themselves.

Some theories of similarity hypothesize a process whose inputs are representations in the form of feature

lists with most of the properties represented as unitary attributes (Nosofsky, 1986; Tversky, 1977). According to others, conceptual knowledge plays such an important role in similarity, that similarity is taken to be akin to analogy; operating on an interconnected system of relations and their arguments (Gentner & Markman, 1997). The crux of this view is that processes of similarity, as well as difference (Markman, 1996), operate by aligning the structures of the compared entities. The structures themselves are described as a system of relational predicates and their attributes. The research program of structural alignment (see Gentner & Markman, 1997) convincingly demonstrated that the use of structural knowledge is an integral part of making similarity judgments.

It is an open question, however, whether the *only* kinds of information used for these judgments are in the form of such a-modal representations as relations or feature lists. A recent proposal (Barsalou, 1999), suggests that perceptual states - modal and analog forms of representation - are *also* used to support higher cognitive processes. Perceptual states are taken to maintain a part of the perceptual nature of their referents, without being transduced into a representational language. If this is the case, judgments of similarity and/or difference might make use of perceptual information, in addition to other forms of knowledge.

We examined this issue by evaluating the effects of various types of presentation conditions on similarity and difference judgments, which were made for a variety of natural stimuli. We presented participants with pairs of items for similarity and difference judgments under three presentation conditions which were manipulated between groups: pairs were presented as Words-Only (WO), as words accompanied by pictures (WP) or as pictures only (PO). The instructions given to all three groups were the same, and did not make any reference to speed of response. Most critically, the instructions given to participants in the Word-Only condition did *not* mention envisioning the objects depicted by the words. If participants in this

group took longer to reach their decision, but ultimately made judgments resembling those made in the picture conditions, this would suggest that perceptual information was recruited when making these judgments.

The reported research has two major goals: (1) to estimate effects of perceptual and non-perceptual aspects of the stimuli on making judgments of similarity and difference; and (2) to examine whether perceptual and non-perceptual aspects of the stimuli affect the relation between the similarity and difference scales.

Calibration Experiment

The purpose of the calibration study was to choose pictorial material that would be easily and unambiguously recognized as typical examples of the intended items. Twenty-seven undergraduate students from the Ohio State University participated in the study. The photographs chosen corresponded to 100 items, taken from 10 categories of Battig and Montague's (1969) category norms with 10 items being selected from each category. The ten categories belonged to two ontological domains, living things and artifacts, with five categories in each domain. In addition to the experimental items, 25 items that appeared to be bad examples of their types were also added as negative anchors. Participants were presented with photographs of objects followed by words denoting these objects, and decided whether the photographs were good examples of the entities depicted by the words ("something that immediately reminds you of that thing"). For example, a picture of a car was displayed, followed by a blank screen and then by the word *CAR*. Participants pressed 1 if the photo was indeed a good example and 0 if it was not.

The proportion rating for the experimental items was 0.85. We included only those photographs that were found to be good depictions by more than 67% of the participants. This procedure resulted in the removal of 10 items.

Experiment 1a: Judging Similarity and Difference of Objects Denoted by Words

Method

Participants There were 29 participants in the similarity-judgment condition and 25 participants in the difference-judgment condition. The participants in both conditions, and in all following experiments, were undergraduate students from the Ohio State University who participated to fulfill a psychology course requirement or in return for payment.

Design and Materials The experiment had a mixed design with Judgment type (similarity judgment or difference judgment) as a between-subjects variable and

Pair-type (same-superordinate, within-ontological domain or across-ontological domains) as a within-subjects variable. The 90 items chosen from the calibration test were used. Items were paired to construct 240 pairs of items such that: (a) 80 pairs were of items from the same superordinate category, (b) 80 pairs were of items from different superordinate categories but from the same ontological domain (i.e., both were either artifacts or living things) and (c) 80 pairs were of items belonging to different ontological domains. We decided to use such pairs since there was ground to suppose that they differ considerably in their perceived similarity (see Markman & Wisniewski, 1997).

Procedure The participants worked alone in an experimental room. Participants making similarity judgments were told that their task was to decide how similar these items were. They were instructed to press 3 if items were very similar, 2 if they were not so similar, and 1 if they were not similar at all. Participants making difference judgments were told that their task was to decide how different these items were. They were instructed to press 3 if items were very different, 2 if they were not so different, and 1 if they were not different at all. The experiment was run in three blocks, with a 1-minute break between blocks. The experiment began with a few practice pairs, which were followed by 14 hidden practice pairs whose purpose was to bring participants up to speed. Practice items were not analyzed.

Results and Discussion

Reaction time data and ratings for similarity and difference judgments are presented in Table 1. Note that ANOVA results will be presented in the overall-analysis section, whereas the results of t-tests are presented in Table 1.

Table 1. Reaction times and ratings for similarity and difference judgments in the Word-Only condition

Pair type	Reaction Time		Ratings	
	Sim	Dif	Sim [*]	Dif ^y
Across-domain	1232 _a	1245 _a	1.04 _a	2.99 _a
Within-domain	1315 _b	1317 _b	1.20 _b	2.90 _b
Within-superordinate	1400 _c	1511 _c	2.32 _c	2.06 _c
Average	1315	1358	1.52	2.65

Note. Numbers with different subscripts in a given column differ at $p < .0001$.

^{*} High numbers reflect greater similarity

^y High numbers reflect greater difference

As expected, similarity and difference ratings for the different pair types were different, with Within-

Superordinate pairs (e.g., dog – cat) being more similar than Within-Domain (e.g., shark – horse) pairs, and the latter being more similar than Across-Domain (e.g., cow – spoon) pairs. The difference ratings showed the same pattern. More importantly, reaction times in both the similarity and difference judgment groups were fastest for Across-Domain pairs, slower for Within-Domain pairs and slowest for Within-Superordinate pairs. As will be shown, this pattern of results replicated in the Word-Picture and Picture-Only presentation conditions as well.

Experiment 1b: Judging Similarity and Difference of Objects Depicted by Words and Pictures

Method

Participants There were 18 participants in the similarity-judgment condition and 18 participants in the difference-judgment condition.

Design, Materials and Procedure Design, Materials, and Procedure were identical to those in Experiment 1a, except that items were denoted by words and by pictures, such that the words were printed above the pictures.

Results and Discussion

Reaction time data and ratings for similarity and difference judgments are given in Table 2. The overall pattern of reaction time and rating results was similar to that in experiment 1a.

Table 2. Reaction times and ratings for similarity and difference judgments in the Picture-Word condition

Pair type	Reaction Time		Ratings	
	Sim	Dif	Sim ^x	Dif ^y
Across-domain	1002 _a	1180 _a	1.04 _a	2.96 _a
Within-domain	1123 _b	1177 _b	1.23 _b	2.84 _b
Within-superordinate	1270 _c	1376 _c	2.37 _c	1.82 _c
Average	1131	1211	1.55	2.54

Note. Numbers with different subscripts in a given column differ at $p < .0001$.

^x High numbers reflect greater similarity

^y High numbers reflect greater difference

Initial inspection demonstrates that reaction times in this presentation mode were faster than in the Word-Only presentation condition. Though several theoretical explanations for this may exist, it was important to examine one in particular; namely, that participants were ignoring the words and basing their decisions solely on the pictures.

To examine whether participants were reading the words, we modified the experiment slightly to include 12 inconspicuous spelling mistakes. If participants were paying attention to the words, reaction times for these changed items should be higher than reaction times to the same items in the original experiment. Thirteen participants participated in the modified version of the similarity-judgment condition. The average reaction time for the modified items (1453 ms) was significantly higher than for the original, items (1170 ms.; one-tailed t -test, $t_{22} = 2.37$, $p < .01$). In addition, we asked participants whether they had noticed anything during the study. All but two noticed a few spelling mistakes. The results indicate that participants were indeed reading the words presented above the pictures, and that the reduced reaction times could not be attributed to such neglect.

Experiment 1c: Judging Similarity and Difference of Objects Depicted by Pictures

Method

Participants There were 25 participants in the similarity-judgment condition and 26 participants in the difference-judgment condition.

Design, Materials and Procedure Design, Materials, and Procedure were identical to those in Experiment 1a and 1b, except that items were now depicted only by pictures. Participants were told that they would be presented with pictures referring to objects in the world, and that their task is to determine how similar these objects are.

Results and Discussion

Reaction time data and ratings for similarity and difference judgments are given in Table 3. The overall pattern of results was as in experiments 1a and 1b. The fact that the similarity ratings increased and difference ratings decreased the more conceptually related the objects were, testifies to the fact that participants used conceptual knowledge in their judgments of pictorial material, and did not rely exclusively on perceptual information. Reaction time data and ratings of similarity and difference are given in Table 3.

Table 3. Reaction times and ratings for similarity and difference judgments in the Picture-Only condition

Pair type	Reaction Time		Ratings	
	Sim	Dif	Sim ^x	Dif ^y
Across-domain	1067 _a	1159 _a	1.03 _a	2.92 _a
Within-domain	1154 _b	1171 _b	1.21 _b	2.74 _b
Within-superordinate	1334 _c	1316 _c	2.22 _c	1.85 _c
Average	1185	1215	1.49	2.50

Combined Analysis of experiments 1a – 1c

Analysis of Response Times for Difference and Similarity Judgments Under Three Presentation Conditions.

The data from all experiments were combined to assess the effects of the presentation-mode on reaction times in the similarity- and difference-judgment tasks. Average response times were calculated and entered into a 3 (Presentation) X 2 (Judgment) X 3 (Pair-Type) mixed ANOVA, with Presentation (Word-only, Word-Picture and Picture-only) and Judgment (Similarity and Difference) as between subjects variables, and Pair-Type (Across-domain, Within-domain, Within-superordinate) as a within subjects variables.

As expected, the main effect of Pair-Type was significant, $F(2, 250) = 251.5$, $p < .0001$. More important, the main effect of Presentation was significant, $F(2,125) = 10.91$, $p < .0001$. Reaction times in the Word-Picture condition (1138 ms) were faster than in the Picture-Only condition (1183 ms) and the latter were faster than reaction times in the Word-Only condition (1337 ms). Scheffe's post hoc analysis revealed that reaction times in the WO condition were significantly slower than reaction times in the PO and WP presentation conditions ($p < .001$). Judgments in the WO condition were slower than in the other conditions even though the WP condition presented participants with more information, and the PO condition amounted to a naming task. There are several explanations for this effect: it might be that under the different presentation conditions, participants made differential use of perceptual and conceptual information in their judgments; relying more heavily on pictorial data whenever it was available, thus being faster in those conditions that contained pictures. If this is the case, then judgments in the PO and WP conditions should be more similar to each other than to the WO condition. The second possibility, which is consistent with the perceptual-symbols hypothesis, is that participants under the three presentation conditions eventually constructed the same representation, but that this process took longer in the Word-Only condition. If so, judgments in all three modes are expected to be quite similar. An analysis of the similarity and difference judgments was conducted to test these possibilities.

Analysis of Similarity and Difference Judgments Under Three Presentation Conditions.

We now examined the effects of presentation mode on (a) judgments of similarity and difference and (b)

the relation between the similarity and difference scales. We separately analyzed similarity and difference judgments given under the three presentation conditions. Due to the ordinal nature of the response scale, we used the variance of response proportions as the measure of test in the following ANOVAs. However, since the data are more easily encapsulated in the form of averages, we present them in Table 4.

Table 4: Mean similarity and difference ratings under three presentation conditions.

Condition	Mean Similarity	Mean Difference
Picture Only	1.489	2.507
Word Picture	1.548	2.543
Word Only	1.522	2.654

We first analyzed responses given in the *similarity-judgment* groups. The proportions of 1, 2 and 3 responses were analyzed in 3 separate one-way ANOVAs, with Presentation as a grouping factor and response proportion of each response as the dependent variable. No effect was found in any of these analyses ($F_s < 1$). There were practically no differences in the response proportions in the three presentation conditions. Proportions of the three responses varied minimally between presentation conditions; in the range of 1.5%.

A similar analysis was performed on the response proportions in the *difference-judgment* groups. The proportions of 1 and 2 responses did not vary significantly between presentation conditions. However, an ANOVA of '3' responses was significant, $F(2,62) = 5.08$, $p < 0.01$. In the WO condition, there were more '3' responses (74%) than in the other WP and PO presentation conditions (69%, 68% respectively).

The similarity-rating data are congruent with the hypothesis that participants in all presentation conditions performed the similarity judgment on the same representation. Note however that while judgments across all conditions were similar, participants in the WO condition, who were not presented with the perceptual component in the stimuli, were slower to make their judgments.

In addition to this converging measure, the data that are perhaps most suggestive of the use of perceptual information in the WO condition is the fact that participants in the WO condition were also slowest in judgments of Across-domain items (e.g., Pan-Dog). One does not need to envisage a Pan and a Dog in order to determine that they are not similar at all, or very different. Such a decision could easily be made on the basis of categorical knowledge alone. However, judgments of similarity and difference for such pairs in the WO condition were slower than such judgments in

the WP and PO conditions (1232, 1002, 1067 and 1245,1080,1059 ms. for similarity and difference judgments respectively). The difference-judgment data are also congruent with the possibility that participants evoked perceptual data. As reported, difference judgments to Across-domain items in the WO condition were slower than in the other presentation conditions, suggesting that perceptual information was used here as well. However, the slight tendency to find more items 'very different' in the WO conditions may suggest that another mechanism was also at work here. We discuss the issue subsequently.

Analysis of Scale Equivalence Under Three Presentation Conditions

We also computed a measure relating the similarity and difference ratings under the three presentation conditions. To recap, in this analysis we are interested in the relation between an items' perceived similarity and its perceived difference under the three presentation modes. Since it is only sensible to talk of a degree of similarity in cases where similarity was found, we included in this analysis only items whose average similarity was greater than 1.

To compute this measure, for each item whose average similarity score was greater than 1, we compared its location on the similarity scale to its location on the difference scale. Let S_i and D_i denote, respectively, the distance of an item from the "least similar" end of the similarity scale and the "most different" end of the difference scale, in units of standard deviation. In the case of equivalence of the similarity and difference scales, the items' difference between S_i and D_i should be equal to 0 (i.e., an item that was judged "most similar" should be also judged "the least different").

Delta, a measure of deviation from scale equivalence, is the average of the differences between these two parameters when computed across all items. The total deviation from equivalence between the scales then is $[\sum (S_i - D_i)]/N$. If scales are equivalent, Delta is equal to 0. Delta is greater than 0 when the judgment of similarity is more conservative than the judgment of difference (e.g., if a pair is judged as "somewhat similar" and also as "very different"). Delta is less than 0 when the judgment of difference is more conservative than the judgment of similarity (e.g., if a pair is judged as "somewhat similar" and also as "least different").

Delta measures for all items, under the three presentation conditions were subjected to a one-way ANOVA with Presentation as a between-groups factor. The main effect of Presentation was significant, $F(2,511) = 40.3$, $p < .001$. Scheffe's post hoc comparisons revealed that all Delta measures differed significantly both from each other and from zero, p 's <

.05. Delta measures, the number of pairs on which Delta was greater than zero and the number of pairs on which Delta was lower than zero for each presentation condition are given in Table 5.

Table 5: Delta ratings and proportions for three presentation conditions.

Condition	Delta	Pairs where Delta > 0	Pairs where Delta < 0
Picture-Only	- 0.08 _a	57	108
Word-Picture	0.09 _b	109	54
Word-Only	0.16 _c	146	38

Note. Numbers with different subscripts in a given column differ at $p < .05$.

In the Picture-Only condition, items tended to be located 'farther' from the "very different" end of the difference scale than they were from the "not similar" end of the similarity scale. However, for the Word-Picture condition, and especially the Word-Only condition, items tended to be 'closer' to the "very different" end than they were to the "not similar" end. In short, negative Deltas in the Picture-Only conditions stem from more conservative ratings of difference compared to the similarity ratings given.

A possible explanation is that the presence of words resulted in more weight being given to conceptual knowledge in judgments. It has been suggested that in certain conditions, difference judgments are based on a comparison that involves aligning the structure of the items in the pair (Markman, 1996). Since conceptual knowledge affords a basis for structural alignment, it might be that the presentation of words resulted in enhanced attention to these differences. For instance, a pair such as 'dog - cat' might be judged highly similar when presented under all presentation conditions. However, when greater weight is given to conceptual knowledge, one might remember that dogs bark and cats meow, that dogs can become attached to people and cats are territorial, and that dogs bite and cats scratch. Minding these differences could lead to more extreme difference ratings.

General Discussion

We set out to examine the effects of various presentation modes on perception of similarity and difference in order to establish what information is used in such judgments, and how the presentation modes affect the similarity and difference scales themselves. We used Reaction times, and similarity and difference ratings to address the first issue, and used Delta, a measure of asymmetry between the scales to address the second.

In short, two major findings stem from the three reported experiments: (1) When pictures were not

present, reaction times were slower than in the other presentation conditions, but the judgments were comparable with them and (2) Deltas were positive whenever words were present, and were negative whenever words were absent. These data may be indicative of several important regularities.

First, people may rely on both perceptual and conceptual input when making similarity/difference judgments. In particular, their responses are faster when words are accompanied by pictures than when words are presented alone. It seems reasonable to hypothesize that they try to envision objects when those are depicted by words alone. Particularly suggestive of this, is the fact that compared to the Picture-Only and Picture-Word conditions, participants in the Word-Only condition were also slower in responding to Across-domain pairs. Other research on the role of perceptual information in higher-level cognitive tasks supports this possibility. Recent studies have demonstrated that accessing perceptual knowledge is an integral part of such tasks as property generation and property verification (Solomon & Barsalou, 2000; Wu & Barsalou, 2001). Though the data support the hypothesis that people did use perceptual information, the issue can be conclusively resolved by obtaining activation measures from brain areas implicated in imagery during the performance of this task.

Second, the Delta measure refers to what may be different processing considerations under the Word-Only and Word-Picture conditions, on the one hand, and the Picture-Only condition on the other. Particularly, in the former two conditions, Deltas were largely positive, whereas in the latter condition they were largely negative. Recall that the more that difference is underestimated per a given similarity rating, the larger the Delta. Therefore, negative Deltas in the Picture-Only condition stemmed from more conservative ratings of difference compared to respective similarity ratings. These data may point to the effect of knowledge on the perception of difference. They also indicate that regardless of the pair type, judgments of similarity and difference are affected by the modality of input.

Overall faster response times for different pairs than for similar pairs are indicative of the fact that judgments "not similar" or "very different" are made whenever no sufficient similarity is found. At the same time, computation of the degree of similarity is a more lengthy process. The results reported here seem to establish a boundary condition for situations where alignment is used in similarity and difference judgments. Participants were faster to decide that objects are not similar than to decide that they are; suggesting that judgment of difference was not based on finding specific differences. We are currently in the process of setting up research for examining brain

activity under the conditions reported here to evaluate whether brain areas involved in imagery are recruited during similarity judgments to words only.

Abstract

Compound words with irregular plural nouns in first position (e.g. mice-eater) are produced far more frequently than compound words with regular plural nouns in first position (e.g. *rats-eater), (Gordon, 1985). Using empirical evidence and neural net modelling, the studies presented here demonstrate how a single route, associative memory based account might provide an equally, if not more, valid explanation of this phenomenon than the standard dual mechanism based theory (Marcus, Brinkmann, Clahsen, Weise & Pinker, 1995).

1. Introduction

1.1 The Compounding Phenomenon

Psycholinguistic research has shown that English compound words with irregular plural nouns in first position (e.g. mice-eater) are produced far more frequently than compound words with regular plural nouns in first position (e.g. *rats-eater), (Gordon, 1985).

1.2 The Dual Mechanism Model's Explanation of Compounding

The dual mechanism model (Pinker, 1991), proposes that irregular nouns and their plurals are stored as memorised pairs of words in the mental lexicon (e.g. mouse-mice) but that regular plurals are produced by the addition of the /s/ morpheme to the regular stem at a post lexical stage (e.g. rat + s = rats). Compounds are created in the lexicon. Thus as irregular plurals are stored in the lexicon they are available to be included within compound words. However, as only the singular stems of regular nouns are stored in the lexicon the plural form is never available to be included within compound words (Marcus et al, 1995).

1.3 A Single Route Associative Memory Based Explanation of Compounding

An alternative explanation of this compounding phenomenon based on the frequency and patterns of occurrence of items in the linguistic input has not been explored fully. However an explanation of this sort may

explain the treatment of both regular and irregular plurals in compounds (Murphy, 2000). Frequency counts of a sample of the CHILDES (Child Language Data Exchange System) corpora (McWhinney & Snow, 1985) have shown that the plural /s/ morpheme is a perfect predictor of word finality and furthermore, the plural /s/ morpheme is never followed by a second noun. Importantly, the reverse pattern is found with the possessive /'s/ morpheme since it is always followed by a second noun. Therefore, it might be that a noun rarely follows the regular plural /s/ morpheme (i.e. patterns such as "rat/s/ chaser" do not occur) because the pattern "noun – morpheme /s/- noun" is reserved for marking possession (such as rat's tail). Interestingly in other languages that do not have this competition between the plural and possessive morpheme such as Dutch (Schreuder, Neijt, van der Weide & Baayen, 1998) and French (Murphy, 2000), regular plurals are allowed within compounds. Irregular plurals may, however, appear in English compounds as they are not formed by the addition of the plural /s/ morpheme. Thus, irregulars do not compete with the possessive structure and as such may be followed by a second noun in a compound. This polyfunctionality of the /s/ hypothesis is explored here using three neural net simulations and an empirical study.

2. Neural Net Modeling

An associative memory-based account of inflectional morphology has been investigated in numerous connectionist models. Several models have successfully simulated the putative dissociation between regular and irregular inflection for both verbal morphology (Daugherty & Seidenberg, 1994) and plural morphology (Plunkett & Juola, 1999) using a single learning mechanism and no explicit rules. Furthermore, as well as being able to learn mappings from input to output, connectionist models have also been able to learn sequential mappings (Elman 1990). Thus it is predicted that a single route associative memory system could learn that the inclusion or omission of the regular plural morpheme /s/ is influenced by where that /s/ morpheme occurs in a sequence of language input. Three neural net

models are considered here. The first investigates whether the presence of /s/ predicts word finality. The second and third models analyse whether learning about the word that follows an /s/ morpheme is sufficient to drive learning about compound formation in English.

2.1 Experiment 1.

Experiment 1, was designed to test the degree to which /s/ indicates word finality in a stream of concatenated letters. A neural network was trained on a concatenated stream of 200 sentences of child directed speech taken from CHILDES (MacWhinney & Snow, 1985). A word-ending marker was attached to each word and the words (including a word-ending marker) were concatenated to form a stream of 3596 letters. The network was trained on 200 passes through the sequence of letters. Each letter was encoded using one of 26 random 5-bit vectors (one for each letter in the alphabet). The word-ending marker was encoded using a 27th 5-bit vector. The network was required to predict the next letter it expected to occur given the letters it had seen previously. The network consisted of 5 input units, 30 hidden units, 5 output units and 35 context units. A fully recurrent and a SRN (Elman, 1990) architecture were tested and produced similar results. It was hypothesised that on a next letter prediction task of this kind, a neural network would learn that after the input /s/ there was a high probability that the next input would be a word ending marker.

Test Set And Results: As predicted, at the beginning of a word the error was high but as more letters were presented to the network the error decreased until it was at its lowest at the end of the word. The network's ability to learn that [-s] is a good predictor of word finality was tested using 19 unseen words that ended in /s/ and 19 unseen words that ended in other letters. The network was more accurate (i.e. the error was lower) at predicting a word ending marker after an /s/ than after all other letters combined ($t = -2.08$, $df = 18$, $p < 0.05$). This simulation was completed to confirm that a model with a single learning mechanism and no explicit rules, trained on child directed speech, could learn that after /s/ there was a high expectancy that the next item would be a word-ending marker. Interestingly, /s/ is associated with word finality even though /s/ appears in the middle of numerous words. This overwhelming pattern of /s/ at the end of a word may influence language learners to omit /s/ from the middle of words such as compounds.

2.2 Experiment 2.

The aim of this experiment was to examine how highly consistent patterns in the input (i.e. that a plural noun is never followed by another noun while a possessive noun is always followed by a second noun) might drive learning about how to manipulate plurals within noun-noun compounds. The network was required to predict the

next word it expected to occur given the words it had seen previously. It was impossible for the network to predict the exact word that followed in the input. However, the network was expected to learn which syntactic category the next item would come from. Thus the network was expected to make a first order distinction between the function of nouns and verbs, determiners and adjectives (Elman, 1990). Furthermore from these induced syntactic categories the network was expected to learn a second order distinction that only "verbs" could appear after some /s/ morphemes and only "nouns" could appear after other /s/ morphemes. It was impossible for the network to distinguish between the possessive and the plural /s/ as both were encoded in exactly the same manner in the input. However, the network was trained on one group of words that were represented as having the properties of possessives, plurals and singulars, a second set was only represented as singulars and plurals and a third group was only represented as singulars and possessives. It was predicted that the tokens making up these three groups of words would cluster together as three distinct sets in the hidden layer representations. The network was trained on a concatenated stream of 2000 legitimate English sentences constructed from a lexicon of 38 words. A sentence-ending marker was attached to each sentence and the sentences (including the sentence-ending marker) were concatenated to form a stream of 14,600 words. The network was trained on 10 complete passes through the sequence of words. Each word (including the sentence-ending marker) was encoded using a 39-bit localist coding scheme. The presence or absence of /s/ at the end of a word was also explicitly coded. A simple recurrent network was used so that at any point in time the state of the hidden units at the previous time step were used as additional input (Elman, 1990).

Results: Figure 1, shows a typical representation of the first two principal components of the hidden unit representations. The dotted line superimposed on the PCA diagram shows the divide between the way nouns and verbs are represented in the hidden units. The network has also represented determiners and adjectives separately. Most interestingly, nouns which were included in the training set as both "plurals and possessives", items that were only included as "possessives" and items which were only included in the "plural" form are all represented separately within the cluster of words ending in /s/. Therefore, Experiment 2 showed that a neural net was able to make some differentiation between the plural and possessive /s/ depending on the words that followed it in the input even though the two types of /s/ had exactly the same encoding characteristics.

Figure 1. First two principal components of the hidden layer representations in Experiment 2. Area 1 corresponds to the representational area occupied by items that appeared in the context of both plurals and possessives. Area 2 corresponds to the representational area occupied by items that appeared only in a possessive context and area 3 corresponds to the representational area occupied by items that appeared only in the plural context.

2.3 Experiment 3.

In Experiment 2, the network was able to group nouns that in the training set were behaving as “plural and possessive” or as “plural” or “possessive” only. However, the network could not totally disambiguate plurals from possessives. In this third simulation, the network that was used in Experiment 2 was amended to include an extra input unit that encoded whether the subject of the sentence in which the word occurred was either a plural or a singular noun. Hence, although both “plural” and “possessive” words were coded as ending in /s/, only plural items were encoded as ending in /s/ and being plural, as possessive words were encoded as ending in /s/ but being singular. The same training set and task from Experiment 2 was employed. With the addition of this minimal semantic information, the network is expected to disambiguate “plural” nouns from “possessive” nouns. It was predicted that in the hidden units, the plural and possessive nouns would be represented separately.

Results: Figure 2, shows a typical representation of the first two principal components of the hidden unit representations. From the PCA it is evident that once again nouns, verbs, determiners and adjectives are represented separately in the hidden units. With the addition of the semantic information it is now evident that singular, plural and possessive nouns are all represented separately. Singular and possessive nouns (both of which are actually singular nouns) are located in a similar

position but plural nouns are now represented quite separately. Interestingly, both plurals and singulars i.e., items that may be followed by a verb lie in similar positions on the x axis, while the possessives are clustering with adjectives i.e., with other items that are followed by nouns. Therefore, Experiment 3 shows that learning about the different functions of the /s/ morpheme is enhanced with the addition of the very minimum of semantic information

Figure 2. First two principal components of the hidden layer representations in Experiment 3

2.4 Discussion of Neural Net Modelling

From Experiment 1, it is evident that a neural net model trained on child directed speech was able to learn that /s/ is strongly associated with word-finality (even though /s/ occurs frequently in the middle of words). This overwhelming pattern of /s/ at the end of words might influence English language learners to omit /s/ from the middle of words such as compounds. Experiment 2, showed that the net was able to learn that /s/ followed by one set of words was different from /s/ followed by a different set of words even though the /s/ was encoded in exactly the same way in the input. The same might be true for the language learner. Both the possessive /s/ and the plural /s/ sound the same phonetically but the patterns in which the two different types of morpheme appear in the input may be sufficiently distinct as to indicate that one type of morpheme performs a specific linguistic function and the other performs another type of linguistic function. From Experiment 3, it is evident that learning that the plural and possessive morphemes are only legal in certain sequences may be refined as the child learns that semantically, the plural morpheme refers to many things while the possessive morpheme usually refers to one thing.

Table 1: Examples of Compounds used as stimuli in Experiment 4.

Group	Example of contextualising sentence	Examples of compounds
(1) Possessive nouns	Last week, I left my purse in a London taxi. Luckily, I managed to signal to the	taxi's driver
(2) Regular plural nouns	I feed four cats, a Burmese, a Siamese and two lovely old Persians. I enjoy being a	cats feeder
(3) Irregular plural nouns	Women always get lowly jobs. In the nursery rhyme the farmer's wife is nothing more than a	mice chaser
(4) Comparatives or superlatives	Greg is very modest. He was amazed to hear that his song is still the record company's	biggest seller
(5) singular nouns ending in phoneme /s/	We'll have a larger lawn and mowing the grass will take longer. I'm thinking of employing a	grass cutter
(6) singular nouns ending in a phoneme other than /s/	Stephen is so skilled at mixing cocktails that the hotel want him to work permanently as a	drink server

3. Experiment 4:Compound Processing Study

The compounding phenomenon was further tested by asking 22 native adult English speakers to process "noun-noun" compounds as part of an "on-line" lexical decision (LD) task. This is important as most research has focussed on production (e.g., Gordon, 1985; Murphy, 2000). In this experiment, participants were required to categorise 216 compounds as being words or non-words having seen them presented visually on a computer screen and proceeded by a contextualising sentence. The mean response time for processing different types of compound (see stimuli) was examined in a within subjects design. Two hypotheses were tested to examine the associative explanation of compounding. These were:- (1) If, as the first neural net simulation (Experiment 1) confirmed, language users associate /s/ with word finality, then compounds in which the first noun ends in /s/ should be processed more slowly than compounds that do not include a first noun ending in /s/. (2) If, as the polyfunctionality hypothesis indicates, /s/ appearing in the middle of a compound made up of two nouns is interpreted as indicating possession rather than plurality, then compounds containing possessive nouns should be processed more quickly than compounds containing plural nouns.

Two further hypotheses were investigated to test the dual mechanism model's explanation of compounding. (1) Pinker (1991) stated that:

"because it categorically distinguishes regular from irregular forms, the rule-association hybrid predicts that the two processes should be dissociated from virtually every point of view.....[including] reaction time" (p 253).

However, the dual mechanism model makes no directional prediction as to which type of morphology might be processed more quickly. Beck (1997) asked native adult English speakers to supply the past tense of a series of present tense regular and irregular verbs. Beck found that both low (mean response time 477 msec) and high (mean response time 508 msec) frequency regulars were produced more quickly than both low (mean response time 581) and high (mean response time 535 msec) frequency irregulars. By collecting reaction times in Experiment 4, it was possible to test the speed at which the two types of morphology were processed within compounds in a lexical decision task. The following two hypotheses were tested, (1) compounds containing irregular morphology and compounds containing regular morphology will be processed at different speeds (2) more specifically, compounds containing irregular plurals and compounds containing regular plurals will be processed at different speeds.

3.1 Stimuli

The first noun in each compound was taken from one of six groups. These were: - (1) possessive nouns (2) regular plural nouns (3) irregular plural nouns (4) comparative or superlatives (5) singular nouns which ended in phonetic /s/ (6) singular nouns which ended in a phoneme other than /s/. Each group of first nouns were matched for frequency. The second noun in each compound was a deverbal noun, i.e., a noun that is formed from a verb (e.g.s, walker, chaser). All second nouns were matched for frequency. Table 1.shows examples of each type of compound tested. The apostrophe was omitted from all the possessive nouns thus making it impossible to

distinguish between the plural and possessive nouns (cf. the neural net used in Experiment 2). However, each compound was preceded by a contextualising sentence, (cf. the neural net used in Experiment 3) which pilot work had shown would lead the first noun in the compound (e.g., rats in *rats eater) to be interpreted appropriately. To ensure uniform treatment of all stimuli, contextualising sentences also preceded the first noun even where they were not taken from the plural or possessive groups (see Table 1. for examples of contextualising sentences).

3.2 Results

Table 2. Mean reaction times

	Mean reaction time in milliseconds	Standard deviation of Mean reaction time	Difference between means in milliseconds
Comparisons to test the associative account			
All groups ending in /s/	1285	465	
Final phoneme other than /s/	1205	455	80*
Regular plurals	1277	492	
Possessives	1191	437	86*
All groups containing regular morphology	1231	450	
Irregular plurals	1339	470	108*
Regular plurals	1277	492	
Irregular plurals	1339	470	62
Comparison to test the time difference between processing plurals and processing other types of morphology			
Regular and irregular	1291	479	
All other items of morphology	1188	424	103*

* Difference reliable at $\alpha = 0.05$

Mean reaction times in milliseconds are shown in Table 2. Two planned comparisons were conducted to test the associative explanation of compounding. Firstly, compounds with a first noun ending in /s/ were processed more slowly than compounds where the first noun ends in another letter (a mean difference of 80 milliseconds) ($t=4.41$, $df=21$, $p<0.05$). It took participants an average of 86 milliseconds longer to process compounds containing

regular plurals than compounds containing possessive nouns ($t=2.195$, $df=21$, $p<0.05$). These two findings support the outcomes of the neural net simulations in Experiments 1, 2 and 3. Two planned comparisons were conducted to test the dual mechanism model's explanation of compounding. All types of regular morphology were processed more quickly than irregular plurals (mean difference of 108 milliseconds) ($t=3.22$, $df=21$, $p<0.05$). It took participants an average of 62 milliseconds longer to process irregular plurals than regular plurals but this difference was not found to be reliable. A post hoc analysis was also conducted to test the difference between the time taken to process compounds containing both types of plural and the time taken to process compounds containing other types of morphology (mean difference of 103 milliseconds). A Tukey's HSD test found this difference to be reliable ($F=11.29$, $df=21$, $p<0.05$).

3.3 Discussion

Consider first the two hypotheses that tested the associative explanation of compounding. It took longer to process compounds in which the first noun ended in /s/ than compounds which did not include a first noun ending in /s/. Language users, like the network in Experiment 1, found it harder to process /s/ in the middle of a word. Furthermore, possessive nouns are easier to process than plural nouns in the middle of compounds even though they share exactly the same phoneme. The /s/ morpheme in the middle of a word seems to indicate possession not plurality. Consider next the two hypotheses that tested the dual mechanism's explanation of compounding. Similar to Beck's (1997) production data, it took participants in this experiment less time to process all types of regular morphology than it took them to process irregular plurals (the only type of irregular morphology tested). However, no difference was found in the time taken to process regular and irregular plurals, despite Pinker's (1991) prediction that the two types of morphology should be dissociated "from virtually every point of view" (p 253). Interestingly, a reliable difference was found when reaction times to both types of plural were collapsed together and compared with reaction times to comparatives and superlatives and possessives (all items of regular morphology) collapsed together. Adult language users find it relatively difficult to process either type of plural in the middle of compounds. However, contrary to the predictions of the dual mechanism model, adults seem to have no difficulty processing other items of regular morphology (i.e., items which are produced at a post-lexical stage) within compounds (cf. Marcus et al, 1995). It has been argued elsewhere, that due to the competition with the possessive structure, language users omit regular plurals from compounds. Furthermore, guided by this template, i.e., that plurals do not occur within compounds, mature language users also begin to

omit irregular plurals from compounds, (Hayes, Smith & Murphy, unpublished manuscript)

4. General discussion

Experiment 1 showed that /s/ is associated with word finality. Furthermore, participants in the empirical study took longer to process compounds which contained /s/ than compounds that did not contain /s/ (regardless of what type of /s/ it was). Both strands of evidence would seem to indicate that /s/ is linked to word finality despite the fact that /s/ occurs frequently in the middle of many words. This overwhelming pattern of /s/ at the end of words might influence language learners to omit /s/ from the middle of words such as compounds. Evidence from Experiment 2, showed that a neural network was able to learn that /s/ followed by one set of words was different from /s/ followed by a different set of words even though the /s/ was encoded in exactly the same way in the input. From Experiment 3, it was evident that learning that the plural and possessive morphemes are only legal in certain sequences may be refined as the child learns that semantically, the plural morpheme refers to many things while the possessive morpheme usually refers to one thing. The empirical evidence also showed that one type of /s/ morpheme was processed more quickly within compounds than another type of /s/ morpheme, although it was denoted by same phoneme. Both the possessive /s/ and the plural /s/ sound the same phonetically but the patterns in which the two different types of morpheme appear in the input seem to be sufficiently distinct to indicate that one type of morpheme performs a specific linguistic function and the other performs another type of linguistic function. As well as providing support for the associative account Experiment 4 also calls into question the dual mechanism model's explanation of compounding. No difference was found between the time taken to process regular and irregular plurals. However, participants were able to process some items of regular morphology within compounds relatively quickly. It seems to be plurals (of either kind), rather than items of regular morphology, that adults find difficult to process within compounds.

The three models taken together with the empirical work provide evidence for an associative account of compounding. In this associative account the language user relies on properties of the linguistic input itself and not on distinct ways of representing "rules" versus associations to drive linguistic behaviour. More specifically in the case of compounding, the language user learns that the /s/ morpheme tends to nearly always occur at the end rather than in the middle of a word. Furthermore, the language learner is sensitive to the fact that the same /s/ morpheme occurs in different patterns in the input. With the addition of the absolute minimum of semantics, namely the numerical context in which the phrase is uttered, the language learner seems able to

differentiate between the plural and the possessive morpheme. The possessive morpheme may be followed by a second noun but the plural morpheme may not be followed by a second noun. When faced with a noun-noun compound the language user may delete the plural morpheme from the end not because regular items of morphology are different in kind from irregulars and represented as rules but simply because this pattern is used to denote possession not plurality. Thus the dissociation between the treatment of regular and irregular morphology in compounds may result from the fact that one type of morphology is subject to competition with the possessive morpheme but the other is not. As this alternative hypothesis is explored further, it may become apparent that this plural dissociation in compounds is not good evidence to support the dual mechanism model.

Abstract

A body of empirical evidence indicates that interactional context has a key influence on the form and interpretation of language. This paper reviews a series of experiments which indicate that interactional context also plays a key role in the interpretation of drawings and sketches. Two graphical communication tasks, analogous to definite reference tasks, are described. The findings from these tasks show significant parallels between the mechanisms of co-ordination in graphical dialogue and natural language dialogue. Specifically; the coordination of graphical representation types by 'dialogue' participants, the contraction of recurrent 'graphical referring expressions', effects of direct interaction on the use of abstract drawings, and the development of community-specific graphical conventions.

Interactional Context in Dialogue

Conversation is a, if not *the*, key context of understanding for language. People's use of language to represent objects, events and situations is sensitive to, amongst other things; who they are speaking to, the mutual availability of referents, the history of their conversation and their (dis)joint membership of cultural and linguistic sub-communities (Hymes, 1972; Clark, 1998). Evidence for the direct influence of interactional context on interpretation and understanding comes from a variety of sources (see Krauss and Fussell, 1996, for a review). One example is provided by work on the Collaborative Model of dialogue (Schober and Clark, 1989; Clark and Wilkes-Gibbs, 1986). Wilkes-Gibbs and Clark (1992) have shown that full understanding of referring expressions depends on the degree of active participation in conversation by speaker and addressees. Non-active participants in a conversation, such as passive side-participants, overhearers, or bystanders, have more difficulty in interpreting referring expressions than active participants. This is observed even when, in gross informational terms, they are equivalent to active participants.

A second example of the influence of interactional context comes from studies of conceptual and linguistic co-ordination in dialogue. Garrod and Anderson (1987) have shown that conversational partners tend to match or 'entrain' on the form and in-

terpretation of utterances during interaction. Where several types of semantically distinct referring expressions are possible for describing a location, people show a strong preference for matching the type of expression used by their conversational partner. Brannigan, Pickering and Cleland (2000) have observed similar entrainment effects with syntax. Garrod and Anderson (1987) argue that these dialogue phenomena reflect the operation of a basic dialogue co-ordination mechanism which simplifies the processes of production and comprehension in interaction.

Interactional Context in Graphical Dialogue

Intuitively, it might be supposed that graphical representations would be less sensitive to interactional context. One reason for this is that the production and use of drawings and sketches is normally treated, and analysed, as an activity more akin to monologue than dialogue (cf. Scaife and Rogers, 1996). There is evidence, however, that this underestimates both the actual and potential use of drawing activities as a mode of interaction. Anecdotally, drawings are often incrementally produced and modified as part of a conversational exchange. For example, sketch maps and explanatory diagrams form a familiar extension of many routine conversations.

van Sommers (1984) provides evidence from a questionnaire study that approximately half of routine, non-work, drawing activities take place with or for an audience. Although van Sommers does not report how often these interactions involve direct graphical exchanges, his findings demonstrate the variety of interactional contexts in which drawing occurs. The most frequently cited category is the production of sketch maps of a local area, either as part of an explanation or in order to give directions. The second most frequently cited category relates to activities with children including; games and amusements, teaching or helping with homework and helping children learn to draw. Additional categories of 'public' drawing include; sketching of hair, makeup and clothing, sketching house plans, drawing to express feelings, defacing pictures and drawing people.

The collaborative development and modification of sketches is a feature of many specialised work related interactions, such as architect-architect and architect-client (Neilson and Lee, 1994). We estimate that in the architects' practice studied by Healey and Peters (2001) approximately 30% of daily drawing activities occurred as an integrated part of a conversational exchange. Engle (1998) provides experimental evidence that graphics, gesture and language combine in explanatory dialogues to create composite communicative signals (cf. Clark, 1996). Overall, there is a *prima facie* case that sketches and drawings are often closely integrated into interaction and that this may have significant implications for their interpretation.

A second source of scepticism about the role of interactional context in the interpretation of sketches and drawings is the intuition that drawings and sketches are easier to interpret than language. Arguably, many of the interactional influences on language interpretation are associated with the conventional nature of linguistic representation. Coordinated interpretation of utterances requires the concerted application of conventions. Interaction is used to maintain and modify those interpretations. Drawings and sketches can exploit iconicity to provide a less arbitrary form of representation. Consequently, we might suppose that they would be less dependent on interaction to secure their interpretation. This idea is most plausible for, say, sketches of buildings or people but it does not cover the range of uses to which sketches and drawings are put. Explanations involving sketches of Venn diagrams or Euler circles provide perhaps the most obvious counterexample.

Experiments on Graphical Dialogue

The present paper summarises the findings from a series of experiments which, considered together, provide evidence that the interpretation of drawings and sketches is sensitive to interactional context. In particular, that interactional context affects the form, interpretation and understanding of sketches; and that the mechanisms and processes that give rise to these effects show important parallels to those identified for natural language dialogue.

The findings reported below are drawn from experiments involving two basic referential communication tasks, the Concept Drawing Task and the Music Drawing Task, in which pairs of subjects communicate about a variety of concepts using exclusively graphical means. These tasks can be thought of as two-way or conversational variants of the party game 'Pictionary' (TM).

The Experimental Tasks

The basic Concept Drawing Task uses an ordered list of twelve concept words drawn from the categories; places (e.g., "theatre", "art gallery", "museum"),

people (e.g., "Robert de Niro", "Arnold Schwarzenegger", "Clint Eastwood"), television programmes (e.g., "drama", "soap-opera", "cartoon"), objects (e.g., "television", "computer", "microwave"), and abstract concepts (e.g., "loud", "homesick", "poverty"). One participant, the 'Drawer', is given an ordered list of twelve words. Their partner, the 'Chooser', is presented with an unordered list of the same twelve words plus four distractors. The task is for the Drawer to take each word in turn from their list and produce a sketch of it so that their partner, the Chooser, can identify the concept depicted. The aim is for the Chooser to determine the original ordered list of twelve concept words that the Drawer started with.

The basic Music Drawing Task is similar to the Concept Drawing task but uses pieces of music in place of concept words. The pieces are relatively unknown 30 second piano solos in a variety of genres and styles. In the typical procedure, the Drawer and the Chooser are seated in separate rooms. The Drawer listens to a target piece of piano music and produces a sketch of it. The Chooser has two pieces of music, the target and a distractor, and tries to select which piece is the one depicted by the Drawer. Playback of the pieces is self-paced and all drawing takes place on a shared virtual whiteboard which logs the drawing data for analysis (Healey, Swoboda, King, forthcoming).

In both tasks, subjects are free to draw anything they like; the only restriction is that they do not use letters or numbers. The types of drawing produced for each concept or piece of music varies substantially between pairs, some examples are provided in Figures 2 and 3. All things being equal, each pair tends to establish their own conventional solutions to the communication problems posed by the task. Subjects appear to find both tasks enjoyable and engaging and perform them with above chance accuracy.

Effects of Interactional Context

A number of experiments have been performed using these tasks which suggest important parallels between the effects of interactional context on graphical and verbal dialogue. Here we provide an overview of the findings from these experiments and discuss their implications for investigations of graphical representation and models of human interaction.

Interactional Entrainment. One of the simplest pieces of evidence for effects of interactional context on the use of drawing comes from the Music Drawing task. Participants in this task produce drawings that can be reliably classified into two basic types¹; 'Abstract' and 'Figurative' (Kappa = 0.9, N = 287, k = 2). Abstract drawings, illustrated in Figure 1,

¹For ease of exposition a third, 'Composite, type is not discussed here

Figure 1: Example Abstract Drawings from Two Trials of the Music Drawing Task

Figure 2: Example Figurative Drawings from Two Successive Trials of the Music Task

typically involve graph-like representations of e.g., pitch, melody, rhythm or intensity. By contrast, Figurative drawings, illustrated in Figure 2 typically depict recognisable objects, figures or scenes. Where pairs of participants in the task both take the role of Drawer (either by alternating roles or in manipulations in which both participants draw at the same time) they show a reliable tendency to match each another in their use of drawing the Figurative and Abstract drawing types (Healey, Swoboda, Umata, & Katagiri, 2001). As noted above, this pattern of entrainment between the participants in an interaction is also established for semantic and syntactic aspects of utterances in dialogue (Garrod and Anderson, 1987; Brannigan, Pickering and Cleland, 2000). Garrod and Anderson (1987) argue that entrainment constitutes a basic mechanism through which conceptual co-ordination is achieved in dialogue.

Contraction of Recurrent References. The procedure for the Concept Drawing task typically requires pairs to repeat the same set of twelve target words, in different orders, over several trials. This manipulation ensures that each word is drawn, and identified, several times by each pair. This is designed to reproduce the procedure followed by Clark and Wilkes-Gibbs (1986) who investigated the production of recurrent (verbal) referring expressions by conversational partners. Clark and Wilkes-Gibbs found that both the average number of words and av-

Figure 3: A Sequence of 'Robert deNiro's from the Concept Drawing Task

erage number of turns used to refer to a target item (in their case a tangram figure) rapidly declined with the number of repetitions. Experiments with the concept drawing task show the same pattern of reduction. This is illustrated in Figure 3 which shows a sequence of four trials (ordered left to right and top to bottom). Where target concepts recur, the drawings that represent them quickly become simplified. This is indexed both by simple quantitative measures such as the amount of 'ink' and number of lines used, and by their complexity as estimated by human judges and calculations of their visual complexity.²

Experiments to evaluate the effects of these contractions on the intelligibility of the drawings for non-participants are currently in progress. However, it appears likely that they will have a substantial effect. The first drawing in Figure 3 has a number of elements that might allow a non-participating observer to guess the identity of the individual depicted. For example it includes a sketch map of Italy, sketches of a TV and VCR, and an image of a taxi (which refers to a de Niro film). By contrast, the last sketch in the sequence, consisting of a star and a dollar sign would be much harder to decipher.

Effects of Direct Interaction. Experiments with the Music Drawing task have investigated the influence of level of communicative interaction between participants on the type of drawing (Abstract or Figurative) that they produce. The basic contrast is between an interactive and non-interactive version of the task (Healey et al., 2001; Healey, Swoboda, Umata and Katagiri, forthcoming). In the

²The analysis of visual complexity is based on a psychophysical measure developed by Pelli Burns Farell and Moore (in press) and is based on the formula: Complexity = Perimeter² / Ink.

non-interactive version, subjects alternate between acting as Drawer and Chooser on each trial and the whiteboard is configured to prevent the Chooser from drawing. In this version of the task each trial approximates to a single turn in the communicative exchange. In the interactive version the task is altered so that both members of a pair draw at the same time. They have one piece of music each and must determine, using only drawing, whether their pieces are the same or different. In this case there is a richer communicative exchange. In addition to producing drawings of their pieces, subjects employ devices such as arrows, underlining, and circling to query and revise various aspects of their drawings. Each trial in the interactive task thus approximates to a number of 'conversational' turns.

The effect of the difference in level of communicative interaction can be seen in Table 1 (the 'Composite' category refers to drawings that combine Figurative and Abstract elements). Where both members of a pair can interact directly on the whiteboard, they rely primarily on the Abstract drawings. In the non-interactive task, where they are alternating between drawing and choosing, they rely primarily on Figurative drawings.

Table 1: Distribution of Drawing Types in the Music Drawing Task

Task	Drawing Type		
	Abstract	Figurative	Composite
Interactive	59%	21%	16%
Non-Interactive	27%	64%	8%

Further evidence for the importance of direct interaction comes from analysis of the logs of drawing activity (Healey, Swoboda, Umata and Katagiri, forthcoming). The Abstract and Figurative drawing types are not distinguishable in terms of the number of lines or ink (pixels) involved in producing them, nor in terms of the accuracy of responses associated with their use. Considerations of the efficiency or effectiveness of the two drawing types alone do not appear to explain their pattern of use. However, drawing activities overlap approximately 20% more when subjects produce Abstract drawings than when they produce Figurative drawings. This suggests it is the availability of specific mechanisms of communicative interaction, such as the circling and underlining of each others drawings, that is critical to the co-ordinated use of the Abstract drawings.

Community-based Conventions. Perhaps the most interesting parallel between graphical and verbal dialogue comes from experiments on the emergence of graphical conventions in experimental 'sub-communities' (cf. Garrod and Doherty, 1994).

Data from an unpublished experiment with the Music Drawing task demonstrates that, for this task at least, the patterns of co-ordination in drawing style that emerge within sub-communities are specific to those sub-communities (cf. Healey, 1997). The experiment takes place in two phases. In the first 'convergence' phase experimental sub-communities consisting of sub-groups of six people are formed. Subjects themselves are unaware of this sub-group manipulation, from their perspective the experiment consists of a series of rounds of Music Drawing with a different partner each time. During the convergence phase, the composition of pairs is controlled so that they are always made up of individuals from within the same sub-group. This continues for four rounds thus allowing for a history of interactions to build up within each sub-group. On each round subjects perform the interactive version of the Music Drawing Task for 12 trials.

The second, experimental, phase occurs in the fifth round. In this round two conditions are compared; same-group pairs who are composed, as before, of subjects from within a single sub-group and cross-group pairs who are composed of subjects drawn from different subgroups.³ Same-group and cross-group pairs have equivalent task experience and, as noted, are unaware of any sub-group manipulation. Nonetheless they are reliably different in their use of the Drawing types. Multinomial regression analysis shows a reliable effect of the group manipulation on the distribution of Drawing types ($\chi^2_{(3)}=25.44$, $p=0.00$, $n=516$). The percentages are shown in Table 2.

Table 2: Use of Drawing Types in Pairs Drawn from the Same or Different Subgroups

Task Version	Drawing Type		
	Abstract	Figurative	Composite
Same-group	62.7%	11.1%	18.1%
Cross-group	41.3%	32.9%	15.8%

These results indicate that the co-ordination on particular drawing types that develops within the experimental sub-communities is community-specific. Subjects in the cross-group interactions use a more mixed profile of drawing types. This suggests that the graphical conventions established within sub-communities do not readily transfer to interaction outside those communities. Healey (1997) reports parallel results for verbal dialogues about spatial locations. In this case the types of spatial referring expressions established within sub-communities

³The original design employed three experimental subgroups but for ease of exposition only two are reported here.

Figure 4: Reduction in Visual Complexity of Concept Drawings with Repetition in a Round (B1-B3 = Blocks of recurring items within a round)

during the corresponding convergence phase also proved unstable in 'cross-group' interactions.

Data from a community-based version of the Concept Drawing Task also suggests parallels between communities of graphical and linguistic communicators. The task requires a community group of 8 participants to communicate with each of the other 7 over an extended period of time. In the first round of the experiment they work in 4 pairs with both participants drawing each concept 3 times over the course of the round. In the second round the 8 participants are re-paired and again draw the concepts 3 times. After each round they are re-paired again until every participant has encountered each of the others once and only once.

Figure 4 shows how drawings become increasingly simple (on the Pelli et al. measure) as the experiment proceeds. In the first 3 rounds this simplification process occurs across repetitions of the drawings (shown along the x axis of the figure). However, as the shared interaction within the community begins to develop (i.e., after round 4) the initial drawings in a round become as simple as the final drawings in the round. A similar pattern of results emerges for the communicators accuracy at identifying the concepts conveyed by their partners drawings. These findings are consistent with the idea that as a community becomes established through a common history of interaction so the drawings become conventionalised within the community: Drawings become simpler and more readily interpreted by the members of the community.

The implication of these results is that the processes which establish the conventions for producing and interpreting drawings and verbal descriptions operate in a manner that is directly tied to the character and pattern of interactions in which they were developed and used.

Discussion

The aim of providing an overview of a number of experimental results means that much important detail has been elided from the descriptions of experiments and results provided above. Nonetheless, the results summarised above consistently point to the importance of interactional context in graphical communication.

Like referring expressions in conversation, the form and interpretation of drawings is systematically influenced by the character of the interaction in which they occur. Participants in interactions show a strong tendency to match each others representational style and type. If items recur in an interaction, pairs also tend to develop increasingly abbreviated ways of representing them that are difficult for third parties to interpret. These patterns of change in the form of drawings obtain independently of the particular concept or item being represented. In addition to these basic co-ordination processes of entrainment and abbreviation, there is evidence that level of direct graphical interaction available to participants affects the form of representations they use. In particular, the ability to mark up and modify elements of each others' drawings appears to be important to the sustained use of more abstract representations. Lastly, this paper has presented evidence that interactions within sub-communities lead to the development of community-specific conventions for graphical interaction.

The programmatic rationale for investigating tasks, such as those described above, that involve exclusively graphical communication is the potential they offer for comparison with other modes of interaction. The results summarised above suggest significant parallels between the mechanisms that underpin communicative co-ordination in exclusively graphical and verbal exchanges. As noted above, some of these findings can be accounted for in terms of the collaborative model of grounding (Clark and Wilkes-Gibbs 1986; Clark, 1996) and input-output coordination model (Garrod and Anderson 1987, Garrod and Doherty 1994). The importance of interactional mechanisms, such as localisation, to graphical communication also suggests possible parallels with the mechanisms of conversational repair (Sacks, Schegloff and Jefferson 1974; Schegloff 1992). The viability of applying these explanations to the details of graphical communication is the subject of further work.

Diagrams and Descriptions in Acquiring Complex Systems

Julie Heiser and Barbara Tversky (jheiser,{bt}@psych.stanford.edu)

Department of Psychology
Jordan Hall, Building 420
Stanford, CA 94305 USA

Abstract

Complex systems such as a car brake, circulatory system, or legislative system can be conveyed by language or diagrams. Such systems can be presented from structural or functional perspectives. In three experiments, we examine communicating structure and function of mechanical systems (bike pump, car brake, pulley system) by text and diagrams in relation to mechanical ability. By adding arrows, structural diagrams can be enriched to convey functional information. Inferring structure from function was easier than inferring function from structure. Participants high in mechanical ability outperformed low participants except when text perspective matched question perspective. Those with low mechanical ability are at a disadvantage, especially for inferring function from diagrams. Comprehension of complex systems depends in sensible ways on perspective, medium, and ability.

Conveying Complex Systems

When we learn about a new digital camera, attempt to troubleshoot a broken-down car, or try to understand a new finding in neuroscience, we need to understand a complex system. Despite the ubiquity of contact with complex systems, understanding them or interacting with them can be frustrating. The frustrations are due not only to the complexity of the systems but also to the inadequacy of instructions and explanations.

Effective explanations of complex systems have a complexity of their own. Effectiveness depends on the perspective of the information to be conveyed, on the medium of conveying the information, and on the ability and expertise of the learner. Some of these complex interactions have been examined in previous work, though finding generality in the conclusions has been elusive (e.g., Hegarty, et al., 1990; Hegarty, et al., 1993; Mayer & Gallini, 1990; Morrison and Tversky, 2000). More clarity may be achieved by an analysis of the information to be conveyed relative to characteristics of the media and to qualities of individual differences.

Information about complex systems is of two types: structural information, the configuration of parts or topology of the system, and functional information, the sequence of operations and outcomes. The configuration of parts has a spatial or metaphorically

spatial structure, and the sequence of operations has a temporal, causal structure. The primary media for conveying complex systems are language and diagrams. With an increasing emphasis on visual displays of information, we found it important to investigate the success that diagrams have in comparison to text in communicating this information. Structural information should be effectively conveyed in diagrams because diagrams use elements and relations in space to convey actual topology. Furthermore, arrows indicating the sequence of operations can be added to a diagram to convey functional information.

There are conflicting results on the relations between medium and ability. Some studies show that people with low ability benefit from diagrams and others show that people with low ability have difficulties extracting information from diagrams (Hegarty 1992; Larkin & Simon, 1987; Mayer, 1989). An analysis of information perspective may reconcile these conflicting findings. In particular, low ability participants or novices may be able to extract structural but not functional information from diagrams. Functional information must be inferred from diagrams, in contrast to structural information, which is explicit.

Three experiments examine the interactions of medium, content, and ability in the comprehension of complex systems. We use three systems that have been used with success in previous literature, a pulley system (adapted from Hegarty & Just, 1993), car brake and bicycle pump (both adapted from Mayer & Gallini, 1990).

Experiment 1:

Descriptions from Diagrams

Diagrams of complex systems are excellent for conveying structural information as they use space and the elements in it to convey real or conceptual elements and the relations among them. Adding arrows may facilitate conveying functional information as arrows indicate the temporal sequence of operations. Participants were asked to describe what is depicted in a diagram of a complex system, without and with arrows.

Method

Participants

Participants were 67 psychology students fulfilling a course requirement. Thirty-four participants described diagrams without arrows; 8 a car brake, 14 a bicycle pump, and 12 a pulley system (see Figure 1 for example of car brake diagram with arrows). Thirty-three participants described diagrams with arrows; 8 a car brake, 12 a bicycle pump, and 13 a pulley system.

Procedure

Participants were first asked to rate their mechanical ability and prior knowledge of the device given to them on a 1 to 7 scale, 1 = poor, 7 = excellent. In the 3 experiments reported here, participants self-rated their mechanical ability and their prior knowledge of the complex system presented. We chose a self-rated measure as it has been found to correlate with actual mechanical ability and spatial ability (Hegarty & Just, 1993; Heiser & Tversky, in prep).

Participants were shown one of three diagrams: a car brake (Figure 1), bicycle pump, or a pulley system, either without or with arrows and asked to "Please examine the diagram above. On the lines below, write a description of the system in the diagram."

Figure 1: Car brake diagram with arrows (adapted from Mayer & Gallini (1990))

Coding

Self-rated mechanical ability and self-rated prior knowledge of system correlated highly ($r = .78$, $p < .01$). They were averaged to provide a single ability score, ranging from 1-7 (poor-excellent).

Descriptions of diagrams were coded blindly. Two coders divided each description into propositions. Coders were told that a proposition is the smallest unit of meaning in a sentence. For example, in the sentence "the liquid brake fluid travels down the tube," there are two propositions. First, "the brake fluid is liquid" and second, "the brake fluid travels down the tube."

Coders categorized each proposition as structural or functional. Descriptions of the system structure or of

the features of the components (i.e. the shape of a part) counted as structural information. Descriptions of the function of the system, the function of individual parts or the way the parts work together, counted as functional information. In the previous example, the first proposition, "the brake fluid is liquid" was coded as structural. The second proposition, "the brake fluid travels down the tube" was coded as functional. Coders agreed 94%, and disagreements were settled through discussion.

Results and Discussion

There were no main effects for diagram content, self-rated ability or total number of propositions across conditions.

As predicted, participants who described diagrams with arrows produced significantly more functional units of information ($M = 2.24$, $SD = 1.3$) than participants who described diagrams without arrows ($M = 1.26$, $SD = 1.1$), $F(1,61) = 10.9$, $p < .01$. Similarly, participants who described diagrams without arrows generated significantly more structural units ($M = 1.65$, $SD = 1.65$), than those who described diagrams with arrows ($M = .52$, $SD = .62$), $F(1,61) = 13.67$, $p < .01$.

The presence of arrows in a diagram of a mechanical system indicates the sequence of operations of the system. From the temporal sequence, participants readily made inferences to the function of the system, and described it in those terms.

Experiment 2:

Diagrams from Descriptions

Is the use of arrows to convey temporal, causal sequence so established that producers of diagrams will comply? Participants read either a structural or a functional description of a complex system, and produced a diagram.

Method

Participants

240 students in an introductory psychology course at Stanford University participated for course credit. Forty-four participants either did not draw a diagram or did not complete the questionnaire, leaving 93 participants in the functional description group and 103 in the structural description group, distributed fairly evenly across the three systems.

Stimuli

Structural and functional descriptions were written for each of the three systems, the car brake, bicycle pump, and pulley system. Those for the car brake appear in Table 1 and 2. Structural descriptions contain details of parts and their spatial relations, primarily using forms of the verb "to be" or verbs of fictive motion. Functional

descriptions contain actions and consequences primarily using active verbs of motion.

Table 1: Car brake structural description

"The brake or brake drum is a circular structure. Directly inside the sides of the brake drum are two thick semicircular structures called the brake shoes. The brake fluid reservoir is located above and to the side of the brake drum. From the brake fluid reservoir, a tube runs down sideways and then down to the middle of the brake drum. Extending from both sides of the tube in the middle of the brake drum are wheel cylinders surrounding small pistons. Brake fluid can move from the reservoir through the tube to the pistons. The small pistons can move outward toward the brake shoes. The brake shoes can move outward toward the brake drum."

Table 2: Car brake functional description

"From the brake fluid reservoir, brake fluid enters and travels sideways and down the tube. As the brake fluid accumulates at the bottom of the tube, pressure is exerted on the small pistons inside the wheel cylinders. This causes the pistons to push outward toward the brake drum. The outward movement of the shoes causes friction along the inside of the brake drum, slowing the rotation of the wheel."

Procedure

Participants first rated their mechanical ability on a 1 to 7 scale, 1 = poor and 7 = excellent and their specific knowledge of the depicted mechanical system on the same scale. Participants then read a description of one of three labeled systems (car brake, bicycle pump, or pulley) and were asked: "In the space provided below the description, please construct a diagram of what you think the description is trying to convey."

Coding

Self-rated mechanical ability and self-rated prior knowledge of the device were highly correlated, $r = .72$, $p < .01$. They were averaged to produce a single ability score for each participant. Diagrams were coded blindly by two coders for conventional elements, such as arrows or lines, that conveyed either structure or function. There were no disagreements in coding.

Results

As before, there were no effects of mechanical system or for self-rated ability. Of the 196 depictions coded, the only graphical element added was arrows. The arrows were to indicate direction of motion of the mechanical system. As predicted 62/93 (66.7%) who depicted functional descriptions used arrows in their depiction to indicate sequence of operation, whereas 16/103 (15.5%) participants who depicted structural descriptions included arrows, $X^2(N = 196) = 9$, $p < .01$. All 16 who included arrows in depictions from

structural descriptions were high mechanical ability participants (see Figure 2 for examples).

Figure 2. Drawing from structural description (left) and functional description (right) of car brake.

Discussion:

Communicating With Diagrams

Experiment 1 and 2 showed that people readily interpret and produce arrows in diagrams to suggest functional properties of complex systems. For a car brake, bicycle pump and pulley system, diagrams without arrows elicited structural descriptions. Conversely, for structural descriptions participants drew diagrams without arrows but for functional descriptions they drew diagrams with arrows. Moreover, low ability participants were as likely as high ability participants to comprehend and produce arrows to convey function.

The finding that structural diagrams can be effectively enriched by the simple addition of arrows is important, as making inferences from structure to function is one of the major difficulties of understanding complex systems. The next study will examine the roles of structural and functional descriptions and diagrams with and without arrows in comprehending and making inferences about complex systems.

Experiment 3: Learning structure and function from diagrams and text

Complex systems can be described from structural or functional perspectives. The structural aspects of a system are typically easier to convey. However, it is often the functional aspects that are critical for understanding how the system operates and for troubleshooting, error-recovery and high-level problem solving. The previous experiment showed that a simple enrichment of structural diagrams, an arrow, enable functional inferences. Here we examine directly and in detail the relative efficiency of structural and functional text and of diagrams with and without arrows in conveying structural and functional aspects of complex systems. We do this for both high and low mechanical ability participants. This experiment will provide insight into the effects of medium, text or diagram; perspective, structural or functional; and ability, high or

low, on transmission of structural and functional information about complex systems.

Method

Participants and design

Participants were 147 students in an introductory psychology course at Stanford University participating for course credit. Each participant was randomly assigned to one of 8 conditions. 31 to the no arrow diagram condition, 40 to the arrows diagram condition, 33 to the structural text condition, and 43 to the function text condition. Approximately equal proportions of the participants studied the car brake and the bicycle pump. The pulley system was not used in this study. Study time was recorded for all subjects; however, timing was inaccurate for 34 subjects (in random conditions) leaving 113 study times in the analysis.

Procedure

As in Experiments 1 and 2, participants first rated their general mechanical ability and prior knowledge of the specific device (car brake or bicycle pump) on a scale from 1 to 7, 1 = poor, 7 = excellent.

Participants studied a description or diagram of either the bike pump or car brake. In the text conditions, participants read and studied the description four times. In the diagram condition, participants studied the diagrams completely four times. Study time was self-terminating. Immediately after study, participants answered 16 true/false statements, half structural, half functional. The questions varied in difficulty. An example of a structural T/F statement is "The small pistons are adjacent to the brake shoes." An example of a functional T/F statement is "The pistons put pressure on the brake shoes." Participants were told to respond quickly and accurately.

Ability measurements

Participants' scores from the self-rated prior knowledge of device and mechanical ability scales correlated significantly ($r = .68$, $p < .01$) and were averaged to form a mechanical ability score. A median split gave low and high ability students.

Results

Does the medium, text or diagram, or perspective, structural/no arrow or functional/arrow affect performance on structural and functional questions? How does ability affect performance? Because of their natural mapping to space, it is predicted that diagrams will be superior to text for structural questions. In regards to conveying structural or functional perspectives of complex systems, it is predicted that structural descriptions or diagrams should facilitate structural questions and functional presentations should

facilitate functional questions. Finally, which is easier, making inferences from structure to function or from function to structure? To assess these effects and others, we performed four analyses of variance on errors and response times for structural and functional questions. Each ANOVA had medium, text or diagrams; perspective, structural or functional; and mechanical ability, high or low, as factors.

Study time

There was wide variability in study time, but it did not correlate with any of the measures of interest—medium, perspective, or ability.

Learning Structural Information

Effect of Ability

High mechanical ability participants outperformed low ability participants on structural questions. Low ability participants made more errors ($M = 2.5$, $SD = 1.51$) than high ability participants ($M = 1.59$, $SD = 1.14$), $F(1, 139) = 15.7$, $p < .01$. There were no significant differences in response times between high ($M = 4.6s$, $SD = 1.5$) and low mechanical ability ($M = 4.5s$, $SD = 1.3s$). There were also no significant interactions between ability, medium, and perspective for errors on structural questions. Figure 3 illustrates that low ability participants perform close to that of high ability participants when structural text was studied, however this did not elicit a significant interaction.

Effect of Medium

There were no effects of medium for structural questions. Fewer errors were made after a diagram was studied ($M = 1.76$ out of 8, $SD = 1.08$) than after text was studied ($M = 2.28$, $SD = 1.62$), however this difference was not significant, $p > .1$ (see Figure 3). Structure was conveyed equally well by text and diagrams. Response time, however, was significantly longer on structural questions after studying a diagram ($M = 5.1s$, $SD = 1.4s$) than after studying a text ($M = 4.2s$, $SD = 1.3s$), $F(1, 131) = 13.6$, $p < .01$. This effect may be due to extra time required to translate a visual representation into a sentential representation in order to answer the verbal questions.

Effect of Perspective

There were no effects of perspective (structural or functional) on errors or response time on structural questions. Participants made similar numbers of errors on structural questions if a structural perspective was studied ($M = 1.89$, $SD = 1.39$) than if a functional perspective was studied ($M = 2.13$, $SD = 1.41$), $p > .05$. Though in this analysis, diagrams have a clear advantage because structure remains explicit in the diagram with arrows, the interaction between presentation and perspective was not significant, $p > .1$.

The finding that both high and low mechanical ability participants did not differ significantly on structural errors regardless of study perspective indicates that they were able to efficiently make inferences from function to structure.

Figure 3. Errors on structural questions by ability, perspective and medium.

Learning Functional Information

Effect of Ability

For functional questions there was a main effect for ability, where high mechanical ability participants made fewer errors ($M = 1.44$, $SD = 1.3$) than low ability participants ($M = 2.75$, $SD = 1.6$), $F(1, 145) = 29.6$, $p < .01$. There were no significant differences in response times between high mechanical ability ($M = 5.2s$, $SD = 1.9s$) and low mechanical ability ($M = 5.3s$, $SD = 1.8s$), $p > .1$.

Mechanical ability interacted with medium. See the following section for details.

Effect of Medium

There were no overall effects of medium on errors and response times on functional questions. However, medium and perspective interacted, $F(1, 139) = 8.02$, $p < .01$. High ability participants made fewer errors on functional questions when diagrams were studied ($M = 1.1$, $SD = 1.1$) than when text was studied, whereas low ability participants made fewer errors when text was studied ($M = 2.6$, $SD = 1.6$) than when diagrams were studied ($M = 3.0$, $SD = 1.6$). This effect however, could be driven by interaction between perspective of study and medium, where participants performed extremely well if functional text was studied, but not structural text. This is further discussed in the next section.

Interestingly, high ability participants outperformed low ability participants on functional questions in all conditions except when functional text was studied (see Figure 4). These results indicate that low ability participants have difficulties making functional

inferences from structural descriptions and diagrams, with or without arrows. When functional information is presented verbally, low ability participants are no longer disadvantaged.

Effect of Perspective

There was a slight benefit for functional questions from studying functional material, however this effect was only marginally significant, $F(1, 139) = 3.5$, $p = .06$. Performance was higher on functional questions after studying functional text or diagrams with arrows ($M = 1.73$, $SD = 1.48$), than after studying structural text or diagrams ($M = 2.45$, $SD = 1.69$). There were no differences in response times.

There was an interaction between perspective and medium. Errors on functional questions were higher after studying a structural text ($M = 3.0$, $SD = 1.7$) than after studying a diagram without arrows ($M = 1.87$, $SD = 1.5$), functional text ($M = 1.71$, $SD = 1.27$) or diagram with arrows ($M = 1.75$, $SD = 1.68$), $F(1, 139) = 17.48$, $p < .01$. In general, participants were better at making functional inferences from diagrams, than from structural text.

Figure 4: Errors on functional questions by ability, perspective and medium.

Experiment 3 Discussion

Structural information was effectively conveyed by well-constructed diagrams and text, from the perspective of the system's structure or function. Mechanical ability of the participant, however, is important for predicting errors on structural questions.

The results for functional information were quite different. Again, high mechanical ability participants outperformed low ability participants. This result was conditional upon presentation, however, where low ability participants performed as well as high ability participants when functional text was studied. Low ability participants were at their worst when functional inferences had to be made from diagrams.

The results from Experiment 3 help to clarify the relationship between ability and comprehension of diagrams, illustrating the importance of the information

to be conveyed. Low mechanical ability participants were able to learn structure from both diagrams and text, but needed functional text to aid learning functional information.

General discussion

Complex systems consist of structural information, a configuration of parts, and functional information, a sequence of operations and outcomes. The present research investigated the effects of medium, text and diagram, perspective of presentation, structural or functional, and ability on acquisition of complex systems.

Diagrams use elements and relations in space to convey elements and relations in real or conceptual space. Thus, diagrams are especially suited to convey structural information. Experiment 1 and 2 showed that a simple addition to diagrams, arrows, enables a static diagram to convey functional information effectively. Participants spontaneously interpreted diagrams with arrows functionally, and produced diagrams with arrows for functional descriptions. In global acquisition of complex systems, however, arrows were sufficient for participants with high mechanical ability but not for those with low mechanical ability.

In Experiment 3, participants were more adept at inferring structural information from functional than functional from structural. Apparently, function imposes more constraints on structure than structure imposes on function, in accordance with the design adage that form follows function. This means that function is not necessarily transparent from form. This fact is substantiated by the performance of low ability participants, who, in contrast to high ability participants, had trouble making functional inferences from diagrams. Similarly, Suwa and Tversky (2001) found that experienced architects were more likely to extract functional information from their sketches than novices. Low ability participants reached the level of high ability participants when the perspective of the questions matched that of the studied text. This suggests that the text guides the learner in forming a mental model of that information, especially for low ability learners. For this type of complex systems, including car brakes and bicycle pumps, the disadvantages of low ability can be overcome by the addition of explicit functional information.

These results have implications for theories of diagrammatic reasoning. The findings indicate that learners of all abilities are able to extract essential parts and their interrelations from diagrams; however the advantage of diagrams disappears when learners with low mechanical ability are asked to make inferences beyond what is conveyed explicitly in the diagram.

In addition, these results have implications for design of instructions and explanations as well as comprehension of complex systems. Instructions and texts depending solely on diagrams will be ineffective for some users, especially for functional information. Instructional illustrations of mechanical, scientific, or abstract systems such as governmental legislation need to include explanatory text. Taking into account the ability of the learner, the perspective of the information, and the medium in which it is portrayed, will dramatically increase the accuracy and amount of information that can be acquired from a portrayal of a complex system.

Do argumentation tasks promote conceptual change about volcanoes?

Abstract

In the present studies, we assessed college undergraduate research participants' models of the earth's composition and dynamics, both without and with access to a web site on plate tectonics. In previous studies, it has been found that argument writing tasks promote better understanding from web pages, with the best comprehension of texts observed when students write arguments using a two-window browser. In the present investigation, we are interested in whether or not students in this condition acquire more advanced conceptual models of the subject matter than naïve students, or students in other reading/ writing conditions.

In previous studies (Wiley & Voss, 1999; Wiley 2001) the task of writing an argument and the presentation of web pages in two side-by-side windows were found to lead to the most comparison, integration and explanation in student essays. This resulted in better understanding of the subject matter, as measured by inference and analogy tasks. Theoretically, presenting information in multiple sources as well as asking students to construct their own arguments both seem like conditions which may especially prompt active processing, and demand that readers try to develop their own models of the text. (Wiley & Voss, 1999, Perfetti, 1997; Kintsch, 1998). The present studies first investigated what Earth Science concepts students held, specifically pertaining to the causal nature of volcanic eruptions, without receiving any instruction at all. Second, we advanced a taxonomy of student concepts about volcanoes and plate tectonics, and we investigated whether manipulating the writing instruction (essay or argument), as well as the type of web interface (one window or two windows) the materials were presented in, had any effect on the quality of students' causal models of a phenomenon in Earth Science, the eruption of Mt. St. Helens

Earth Science Concepts

Students' understanding of Earth Science concepts is a historically neglected topic that has only begun to receive the necessary attention. Consequently, mental representations of the complexity of our planet and the causes of its natural phenomena is an appropriate topic for conceptual change researchers to focus on as well as an important goal for educators. By the age of 13, most children have acquired a spherical earth concept. They have developed a model of the Earth that corresponds to a planet

(a huge sphere surrounded by space). Vosniadou and Brewer (1992) delineated a series of models that many children hold as they approach a mature understanding of the earth's shape. Most children will acquire a round earth concept by fifth grade. This knowledge alone is an important building block for understanding of many Earth Science concepts, however, there are still important conceptual developments in Earth models that need to occur in order for students to understand many other topics in Earth Science.

For many Earth Science topics, following the adoption of a spherical Earth model, the students need to refine their understanding of the compositional properties and surface features of that model. Specifically, students need to develop models that can account for rock cycles, mountain formation, sea floor dynamics, and geological disasters such as earthquakes and volcanoes. They need to develop models that explain geological data relating to changes in the Earth's surface. This seems to be problematic for many students as they are presented with new Earth Science information.

Generally around fifth or sixth grade, the composition and dynamics of the Earth are included in an Earth Science curriculum. Ross and Shuell (1993) found that students in grades K through 6 had many misconceptions about the causes of earthquakes. Some examples of young children's misconceptions are: that earthquakes are caused by wind or weather; that volcanoes are caused by the heat of the sun or by mountains; and that volcanoes and earthquakes can have animistic/humanistic explanations, like the earth is "upset", and that these events somehow reflect the earth's mood or temperament.

The American Geological Institute (1991) has prescribed the understanding of how the Earth's crust is moving and the Theory of Plate Tectonics as essential questions to be answered by students in grades 9-12. However, even after their first instruction on these topics, students have many misconceptions about the causes of earthquakes and volcanoes. Marques and Thompson (1997) found that sixteen and seventeen year-old Portuguese students held numerous misconceptions about the Earth's continents, magnetic field, and tectonic plate movements. For instance, some students believed that tectonic plates rotate around a

plate axis, while others believed that there is a progressive cooling of the Earth, which causes the crust to crack. Barrow and Haskins (1996) have shown that Earth Science misconceptions extend beyond grade 12 and are exhibited by college students in an introductory geology course, of which less than 7% believed their earthquake knowledge to be good or excellent. Many adults think that earthquakes can be predicted by the weather or the tides. Some still have a model of the earth's surface with continents floating on top of oceans, while others see volcanoes and earthquakes as the result of the earth building up too much pressure, heat or other internal stuff, making the Earth like a balloon or pimple. Clearly, Earth Science is a domain where mastery among children and young adults is rare and misconceptions are widespread.

In one of the few investigations that have been done on people's understanding of advanced Earth Science concepts, Gobert (2000) has found that when younger students attempt to produce causal explanations about Earth Science phenomena, they tend to demonstrate incomplete or distorted knowledge. Gobert (2000) classified student models using typologies of the interior of the Earth and the causal mechanisms of volcanic eruptions. Gobert's typology of explanations for volcanic eruption consists of type 1a models in which mechanisms are heat-related only (like the earth core gets too hot), type 1b models, which involved movement-related causal mechanisms and are void of heat-related causal concepts (like the magma rises or pushes up through the crust and causes a volcano), type 2 mixed models, which contain some elements of heat and movement causal mechanisms but are not elaborate or integrated (the inside of the earth is hot, magma pushes up), and type 3 models, which consist of multiple, well integrated, heat-related and movement-related mechanisms. At level 3 the idea that heat causes movement, and more specifically that convection currents in the earth's core cause tectonic plate movements, is important.

Gobert's typology is a useful one in analyzing and categorizing the models of Earth Science students. With some minor additions and fine-tuning it is utilized in the data analysis in the present studies.

Argumentation Tasks

It is possible that part of the problem with students understanding of Earth Science is that they don't integrate the information that they are presented with into a coherent and complete model. The achievement of this goal could be aided by encouraging students to engage in tasks that facilitate the integration of relevant concepts that are presented to them.

Past work has indicated that argument writing is a task that requires students to integrate information, particularly when it is necessary to coordinate information from different sources to make a cohesive representation of a phenomenon.

Wiley and Voss (1999) found that when students were asked to write arguments about the causes of the Irish Potato Famine from multiple sources it resulted in essays with more transformation, integration, and explanation of the presented information, than when students were asked to write narratives from the same set of sources. Furthermore, students who wrote arguments were better able to identify correct inferences and underlying principles about the causes of the Potato Famine after the writing task. In comparison to students who wrote narratives from textbook chapters, students who wrote arguments from the multiple sources in a web site demonstrated a better understanding of the subject matter. Based on this evidence, Wiley and Voss (1999) concluded that tasks which require students to construct their own representation of a situation yield the most conceptual learning in web-like environments; and the argument writing task promoted understanding because it required students to integrate information from across multiple sources as they created support for a thesis. This result is consistent with other studies demonstrating that tasks that require learners to engage in active, constructive and integrative tasks lead to the best understanding of text (e.g., Chi, de Leeuw, Chiu & LaVancher, 1994; Goldman, 1997; McNamara, Kintsch, Songer, & Kintsch, 1996; Scardemelia & Bereiter, 1987) as well as studies on collaborative discourse which have found that students who engage in more argumentation-related behaviors develop a better understanding from peer discussion (Anderson, et al. 2001; Chinn, Anderson & Waggoner, 2000).

There has been little work studying how students use multiple windows, or looking at optimal conditions for multiple window use (Foss, 1989; van Oostendorp, 1996). Recently, Wiley (2001) found that when readers were given explicit instruction on how to use the browser there were some learning benefits for a two-window interface, while there was an even more resilient facilitation for argumentation task. There appears to be growing evidence that engaging in argumentation, and similar tasks, facilitates conceptual learning and integration of new material.

Present Studies

In the present studies, we assessed undergraduates' models of the Earth's composition and dynamics. In the first study we asked undergraduates for their understanding of what causes volcanic eruptions without providing them with any reading material. In a second study, we tested whether undergraduates would display more mature models after engaging in argumentation tasks. Undergraduates were asked to read documents from a web site about earthquakes and volcanoes either with the general instruction to learn the information so that they could write an essay about what caused the eruption of Mt St Helens, or the specific instruction that they should read the site in order to write an argument of what caused the eruption of Mt St Helens. In addition, students either read the information presented in a single-window or two-window browser. In general, past

work has found that both the two-window design of the browser as well as the argument writing task are responsible for promoting understanding, with the best comprehension of the text observed when students write arguments using a two-window browser. In the present investigation, we are interested in whether or not students in this condition acquire more advanced conceptual models of the subject matter.

An accurate understanding of the nature of the eruption of Mt. St. Helens would entail the following information: Mt. St. Helens is a subduction zone volcano, which means that it is located on a tectonic plate boundary and not on a hotspot. The Earth's tectonic plates are known to move, due to convection currents in the Earth's liquid layers. The plates that lie underneath Mt. St. Helens pushed together, or converge, leading to subduction. Consequently, this subduction (one tectonic plate sliding underneath the other) causes solid mantle from the bottom plate to be pushed down to areas of higher temperature. This solid mantle melts in the high temperature and became viscous liquid magma. Viscous magma builds up and causes an increase in pressure, which is not released until the magma shifts and an eruption occurs.

Study 1 Method

Participants. 28 undergraduates at the University of Illinois at Chicago participated in this experiment.

Procedure. The participants were asked to answer the question "What caused the eruption of Mt. St. Helens on May 18, 1980?". Students were asked to write at least a paragraph.

Measures. Student concepts were assessed by coding answers for the kind of models that students had of how volcanic eruptions happen. The coding scheme was originally based on Gobert's (2000) typology, but several categories needed to be added or amended to account for the models we observed in our protocols. The different levels of our typology are described below.

Student Models of Volcanic Eruptions

It should be noted that some models are not necessarily incorrect explanations of volcanic eruptions per se, because they could account for certain types of volcanoes. But many are not sufficient explanations of why Mt. St. Helens, a stratovolcano, erupted as it did.

Type 0 Incorrect, Superficial Models

Students were assigned a 0 if their explanation of the cause of volcanoes was related to an irrelevant surface feature of the earth. Examples of explanations at Level 0 are that volcanoes are caused by surface conditions, such as wind, avalanches, landslides, mountains, weather, sun, the orbit of

planets, tides, faults, time, dormancy or too much lava, as well as non-explanations. Essays that did not include any of the major causal agents identified below received a 0.

Type 1 Local Models

Models that mentioned single, local causes of movement or heat, as in Gobert's (2000) typology, or the concept *pressure* were assigned a '1'. Models were given this rating if they expressed the idea of one of these three as being the causal agent in the eruption of the volcano. The addition of the concept *pressure* as a type 1 causal agent was made because this concept is a separate notion from heat or movement and is relevant to the eruption of a stratovolcano, such as Mt. St. Helens, in which no gas escapes from the volcano before a violent eruption. A second amendment from Gobert's typology was splitting the movement category into two separate categories, one specifically related to magma or lava movement, and the second related to plate movement. After proposing this coding analysis, none of the students had an explanation related to magma movement alone, so a single movement category was retained.

Explanations of Type 1A tended to mention hot, melting or molten magma, the temperature of the magma, and the heat of the earth's core. Explanations of Type 1B mentioned the movement, shifting, colliding, rubbing or interacting of plates. Explanations of Type 1C tended to mention that the volcano or Earth was full of gas, the magma had too much gas, that there was pressure or that the magma was being kept under force.

Type 2 Mixed Models

Models that included plate movement with either heat, pressure, force or chemical processes were assigned a '2'. In these models, multiple factors were mentioned but not causally related.

Type 3 Integrated Models

Only models that causally related heat or pressure and movement in either direction (i.e. convection currents cause plate movement; or plate movement causes plates to subduct and melt, forming magma that rises under volcanoes) were coded as level 3 models.

Examples of explanations included in the naïve student models along with frequency of occurrence are included in Table 1.

Table 1: Frequency of Naïve Models with Examples

Model	Examples	Frequency (%)
Type 0	I assume that the eruption was due to a geological disturbance such as a sudden misalignment of orbits.	7 (25%)
Type 1A	The eruption of Mt. St. Helens was caused by the heat build up	3 (10.71%)

	in the earth's core...	
Type 1B	The eruption of the volcano was caused by a sudden shifting in the earth's tectonic plates. This shifting caused a disruption of the mountain...	8 (28.57%)
Type 1C	The eruption of Mt. St. Helens occurred because there was an enormous amount of pressure on the volcano... It couldn't keep the lava in, and erupted.	7 (25%)
Type 2	The eruption of Mt. St. Helens was caused by movement in the plates.... The lava is heated to the point where it has to escape.	2 (7.14%)
Type 3	Volcanic eruptions are the result of the earth's tectonic plates shifting below the surface. As the plates move past each other, friction builds up and hot magma forms. Once the plates are pushed to a certain point, the magma is forced up through volcanoes.	1 (3.57%)

Implications

A surprising number of undergraduates have incomplete or incorrect models of why Mt. St. Helens erupted. Consistent with anecdotal reports, there are a number of persistent misconceptions about why volcanic eruptions and earthquakes occur. In study 2, we address the extent to which students may undergo conceptual development as they construct arguments from evidence presented in a web site.

Study 2

Method

Participants. 40 undergraduates at the University of Illinois at Chicago participated in this experiment.

Design. There were two manipulations in this experiment. The first manipulation was in the instructions that students were given. Twenty of the students were asked to read the web site in order to "write an essay of what caused the explosion of Mt St Helens in 1980", while the other twenty were given the exact same instructions except the word *essay* was replaced by the word *argument*.

The second manipulation was in the format of the browser in which the web site was presented. In this experiment, students either read the documents from a single-window browser, meaning they chose documents from a document list that was presented at the start of the experiment, and viewed the documents one at a time. The other half of the students were given a two-window browser, but they also got specific instructions about why they were being given two windows "in order to compare across documents".

Further in this condition the list of documents was split in half, so that in order to read all of the information readers had to use both windows. All students received explicit instruction on how to use the browser environment.

In each of the two presentation conditions, half the students received an essay writing instruction while half received the argument writing instruction. This yielded a 2x2 (writing task x browser format) design with 10 students in each of the four conditions.

Materials. The contents of the page were taken from the USGS web page. Pictures and diagrams were presented with captions, but in their own windows (as documents). There were no hyperlinks between documents other than navigational links back to the overview lists, and between the overview list and the documents.

Procedure. The participants were asked to read documents from a web page about Geological Hazards in order to write either an essay or an argument. All participants were given 30 minutes to read the documents and write their essays.

Measures. Students' concepts were assessed by evaluating the quality of the essays. We coded essays using the coding scheme developed in Study 1. Two raters independently coded each essay, blind to condition. Inter-rater reliability was above .90. Discrepancies were resolved through conversation.

Additionally a demographics questionnaire was administered at the end of the experimental session that included the question, "How much did you know about Mt. St. Helens and its relation to plate tectonics before reading this site?" Participants answered this question on a scale of 1-10, with 1 meaning "not much" and 10 meaning "a lot".

Examples of Student Explanations

The following examples are excerpts of the participants' written essays. Two examples of each category are provided. Only the portions of the essays containing relevant ideas are included.

Type 0 Incorrect, Superficial Model

... the climate has a dramatic effect on volcanoes.

Type 1A Local Heat Model

... in certain locations around the world volcanism has been active for a long time which means there are a hot spots under the plates which are exceptionally hot regions that provide localized high heat energy to use.

...Below some plates there are hot regions which give off high heat energy, thus sustaining volcanism.

Type 1B Local Movement Model

...The earth is built around a dozen plates...As the plates move, it causes the plates to rub against each other, causing

the explosion of the volcano.

...In the case of Mt St Helens, an oceanic-continental boundary formed. A dense plate from the ocean floor meets a less dense plate of continental land, creating the mountainous area around Mt St Helens....The material of the dense plate goes deep into the earth and eventually transforms into magma, a product of a volcano...

Type 1C Local Pressure Model

...The fierce explosion of Mt. St. Helens was due to the fact that gas was trapped inside the magma. This gas can't escape until magma enters the throat of the volcano...

...Mount St Helens violent explosion was due to great amount of silica (in the magma).... These are what stop gases from escaping at the proper time...

Type 2 Mixed Models

...There could be several reasons why Mt. St. Helens erupted. However, I believe a collision of oceanic and continental plates caused the earthquake that caused Mt. St. Helens to erupt...Eventually the Juan de Fuca plate and the North American plate, smashed into each other, causing a great disturbance underneath Mt. St. Helens volcano. The gas inside the volcano could not escape... the pressure built up inside the volcano and grew too strong and came out as one big burst.

...Three plates come into play underneath Mt. St. Helens...The movement of these plates and the added build up of pressure cause a seismic zone to form under Mt. St. Helens...

Type 3 Integrated Models

What produced the explosion of Mt. St. Helens? The explosion could have been caused by the collision of oceanic and continental plates... As the subducting oceanic crust melts within the asthenosphere the new magma rises to the top of the surface and forms volcanoes. Shallow earthquakes are associated with high mountain ranges when intense compression is occurring. Most volcanic eruptions occur near plate boundaries.

The eruption of Mt. St. Helens was caused by the unsettled magma and gas pressure. As plates meet, the denser heavier plate will be forced to sink below the lighter plate. As it moves below, magma is formed as extremely high temperatures below the mantle melt the plate. Gas and magma flow to the surface, pushing until mountains and volcanoes, which will eventually erupt, are formed. They erupt due to this pressure...

Distribution of Models across conditions

The distribution of models by reading, writing and window condition are presented in Table 2. A 2x2 (writing condition x window) ANOVA was conducted on the groups' numerical self-ratings of previous Mt. St. Helens knowledge and there were no significant differences across the experimental groups, ($F < 1$).

Table 2: Frequency of Models by Writing and Window Condition

Model level	0	1	2	3
Narrative				
1 window	3	6	1	0
2 window	1	5	2	2
Argument				
1 window	1	3	5	1
2 window	1	3	4	2
Total	6	17	12	5
Reading	15%	42.5%	30%	12.5%
No Reading	25%	65%	7%	4%

Chi square analysis on the frequency of models by writing condition indicated that models were not evenly distributed. Narrative writers had more models at levels 0 and 1 versus 2 and 3, while argument writers had more models at levels 2 and 3 if anything ($X^2(1)=4.44$, $p < .03$). (An overall chi square analysis on the eight cells was not possible due to low cell size). No effects of number of windows were seen in a chi square on the frequency of models by the windows condition, ($X^2 < 1$).

Implications:

The results of this study indicate that young adults have incomplete models of the Earth's composition and dynamics as indicated by their observed models of the eruption of Mt. St. Helens. Although several students were able to exhibit some understanding of volcanic eruptions in general, many of their models did not show any understanding of the importance of the Theory of Plate Tectonics or that there are different kinds of volcanoes. Generally, students could not accurately describe Mt. St. Helens as a subduction zone volcano, even after reading several documents about the topic that contained all of the necessary information.

Consistent with Wiley (2001) it was found that argument writing did facilitate better understanding and model building from scientific electronic text, while providing a two-window browser only showed a beneficial trend. These results, based on a small number of participants, further suggest that conceptual development, in a domain such as Earth Science, is aided by tasks that encourage integration. But the degree of learning (and the fact that not all students achieved an understanding of plate tectonics and volcanic eruption in this condition) suggests that there may be other pieces of the puzzle needed to advance students beyond their misconceptions in this domain.

It may be that in areas such as Earth Science, where students lack concrete experience with observing and dissecting planets, some concepts are particularly difficult to learn about from text. Additionally Gobert (2000) asserts that plate tectonics concepts are difficult for children to learn due to the large size scales of the agents involved, and the

extremely long temporal scales that extend far beyond a human lifetime. Students may also find it difficult to integrate and visualize these concepts in order to understand the structure and behavior of the planet. Based on the presented studies this holds true for young adults as well. Mastery of this domain essentially requires understanding dynamic spatial information, which may make images, animations and simulations quite important. Although in general, evidence for the beneficial effects of visual adjuncts on learning is mixed (Wiley, in press; Wiley & Hemmerich, in press), for the mastery of these concepts such adjuncts may be critical. We are interested in pursuing this hypothesis, and its effects on long-term learning, in future studies.

Acknowledgments

This research was made possible through the support of the Office of Naval Research and the National Science Foundation by grants to the second author. The authors thank Rebecca Schrader for her assistance in running the experiments.

Abstract

In tune with the 24th Annual Cognitive Science Conference's emphasis on application, this paper presents an empirical comparison between two methods used in agent tracking. The need to predict an agent's intents or future actions has been well documented in multi-agent system's literature and has been motivated by both systematically-practical and psychologically-principled concerns. However, little effort has focused on the comparison of predictive modeling techniques. This paper compares the performance of two predictive models both developed for the same, well-defined modeling task. Specifically, this paper compares the performance of a neural network based model and dead-reckoning model, both used to predict an agent's trajectory and position. After introducing the background and motivation for the research, this paper reviews the form of the dead-reckoning algorithms, the architecture and training algorithms of the neural networks, the integration of the models into a large-scale simulation environment, and the means by which the performance measures are generated. Quantitative measures from our experiments indicate that, for the task considered, the neural network based model provides greater predictive utility, but at an increased cost in processing time. Performance measures are presented over increasing levels of error tolerance.

Introduction

Intelligent agents typically operate in an environment populated by other intelligent agents. Agents may help each other, hinder each other, get in each other's way, or ignore each other, often without directly communicating their intent. In order for an agent to achieve its goals, it is thus sometimes necessary for the agent to determine where the other agents are, what they are doing, and what their

plans are. For example, an agent may want to infer what plan an opponent is executing so that the agent can select countermoves. Han and Veloso (1995), Rao (1994), Rao and Georgeff (1995), Tambe and Rosenbloom (1995), and Tambe (1996) have studied various forms of recognizing an agent's intents.

Sometimes it is necessary to infer facts that are normally observable, such as agent location, because of sensor or other limitations. For example, a pilot agent may need to predict where a threat aircraft is flying after it enters a cloud. There are many approaches to predicting agent trajectories, including Newtonian mechanics (Lin and Ng, 1993), neural networks (Kim et al, 1999), Hidden Markov Models (Washington, 1998) and others. This paper addresses a particular application of trajectory prediction in distributed simulation and compares the effectiveness of a neural network to a commonly used Newtonian approach for this application.

The remainder of this section defines the trajectory estimation problem in the distributed simulation application and describes a previous use of neural networks for estimating agent trajectory in a visual scanning application. The paper then describes a neural network approach for trajectory estimation in distributed simulation and presents results and comparisons with Newtonian dead reckoning.

Dead Reckoning in Distributed Simulation

In a Distributed Interactive Simulation (DIS) (DIS Steering Committee, 1994), simulation software for each agent runs independently of other agents and broadcasts the ground truth about the state of the agent through network packets known as protocol data units (PDUs). Each simulation in DIS uses trajectory estimation so that the state of the agents does not have to be broadcast frequently. Lin and Ng

(1993) explain how dead-reckoning can be used to maintain coherence among entities' states in a DIS environment. Each simulator uses Newtonian equations of motion such as equation 1

$$\begin{aligned} p &= p_0 + (v_0 * \Delta t) + \frac{a_0 * (\Delta t)^2}{2} \\ v &= v_0 + a_0(\Delta t) \end{aligned} \quad (1)$$

where p = current position
 p_0 = initial position
 v = current velocity
 v_0 = initial velocity
 a_0 = initial acceleration
 Δt = elapsed time

to predict the trajectory of other agents. Each simulator also uses the same equation to model the trajectory of its own agent; the output of this equation can be compared to the output of the true dynamics model for the agent to determine when the models diverge. When, and only when, the error between models reaches a certain threshold, the simulator broadcasts new state information for its agent. Figure 1 shows this process in a DIS simulation called ModSAF (Calder et al, 1993) that we used for our experiments.

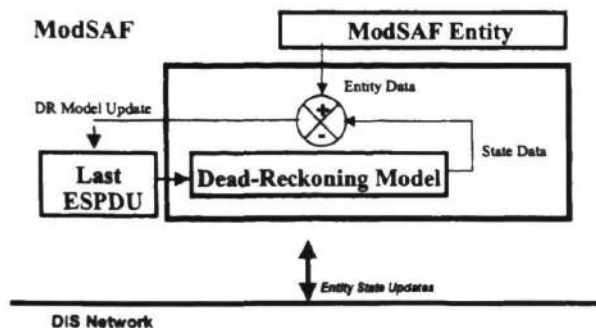

Figure 1. Dead-Reckoning Implementation in ModSAF

Figure 2 shows how at a series of time steps, the true position of an agent computed by the agent dynamics model (shown by the curve) deviates from a linear dead

Figure 2. DIS Dead-Reckoning Process

reckoning model. When the error exceeds the threshold, the models are brought into correspondence by the issuance of an entity state PDU (ESPDU). Thus in the figure, only 3 ESPDUs are broadcast instead of one at every time step. The goal of the research presented here is to reduce the number of ESPDUs sent in by DIS simulations below the number needed using Newtonian dead reckoning.

Neural Networks for Trajectory Estimation

Kim et al (1999) developed a system to generate short-term predictions of an agent's trajectory such that it can be used to predict the agent's position at any future instance, given some window of time. They use this model as part of a helicopter agent's perceptual system to enhance the agent's ability to visually track ground vehicles, and their motivation for this model is both psychologically and practically rooted. Psychologically, this model can be used to simulate a helicopter pilot's gaze shifting as he attempts to visually track and re-require multiple targets. Thus, instead of operating in a state of omniscience, the agent is required to juggle the act of determining spatial information across multiple agents, as would be the human helicopter pilot. The functional ramification of this approach is that the total number of perceptual inputs to the agent is reduced at any given instance. In other words, instead of getting continuous perceptual information on all of the ground entities within the helicopter agent's field of view, by using this predictive model, the agent only requires updated information on entities when its attention is focused on those entities.

The high level architecture of this system is presented in Figure 3. The agent architecture is embedded in the

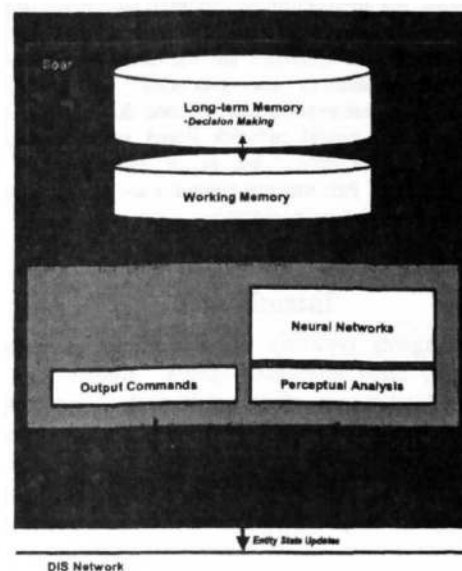

Figure 3. Visual attention for helicopter agent

Modular Semi-automated Forces (ModSAF) simulator, a system used by the military for training and research. ModSAF is elaborated on in section 2, "Methodology". The agent's intelligence is modeled in Soar (Rosenbloom et al, 1993; Newell, 1990). As a model of natural intelligence, the Soar software architecture combines the abilities to react immediately to situations, use knowledge in deliberative decision making, step back from the immediate situation to perform various forms of problem solving and planning, and learn from experience. As an indicator of the maturity and sophistication of Soar-based agents, the system has been used successfully as the production model in a number of large-scale military exercises (Hill et al, 1997; Jones et al, 1999; Nielsen et al, 2000).

The inputs to the neural networks developed for this application consist of entity data (e.g., call-sign, sim-time, position, velocity, etc.) and abstracted terrain information germane to both "on-roads" and "cross-country" travel and correlated to the entity's visual field (hill, road, lake, etc). All together, the input vector consists of 196 fields and the output vector consists of 15 output fields corresponding to discretized changes in heading ranging from -35° to 35° . The selected heading change, coupled with an assumed constant speed and "delta" time since last prediction, can be used to predict the entity's expected location at some time, t . With this prediction, the virtual helicopter pilot is able to look away from the ground entity for up to 7 seconds, within some error threshold.

Methodology

This paper seeks to compare the performance of a neural-network based model with the dead-reckoning model. Like both systems described in sections on dead-reckoning and neural networks for trajectory estimation, this experiment is implemented in ModSAF, a training and research system developed by the Army's Simulation, Training, and Instrumentation Command (STRICOM). ModSAF provides a set of software modules for constructing computer-generated force behaviors at the company level and below. Typically, ModSAF models are employed to represent individual soldiers or vehicles and their coordination into orderly-moving squads and platoons; but, their tactical actions as units are planned and executed by a human controller. The human behaviors represented in ModSAF include move, shoot, sense, communicate, tactics, and situation awareness. The authoritative sources of these behaviors are subject matter experts and doctrine provided by the Army Training and Doctrine Command (TRADOC). ModSAF uses state transition constructs inspired by finite state machines (FSMs) to represent the behavior and functionality of a process for a pre-defined number of states.

The scenario used for the comparison was a road-march for a tank entity 45-segment route shown in Figure 4. It is

approximately 7 kilometers long and takes a tank entity about 15 minutes of simulation time to travel at a March Order speed of 8 m/s. From this 15 minute period, a total of 13760 movement updates were performed, generated at a rate of 15 HZ.

Figure 4. Route Used for Experiment

For this application, a feed-forward architecture developed with back-propagation training was used to develop the neural networks. One of these networks predicts the change in an entity's speed and the second network predicts the change in the entity's heading. Each network used a sigmoid function at the hidden nodes and a linear transformation at the output nodes. The configuration of the networks in each of the models may be seen in Table 1

Table 1. Neural Network Architecture

Model	Arch	Predictors	Resp
Speed	8-20-5-1	$Ra_{t-1}, Rb_{t-1}, Rc_{t-1}, Rp_{t-1},$ $Rs_{t-1}, HRab_{t-1}, HRbc_{t-1}, Hz_{t-1}$	ΔS_t
Heading	7-20-5-1	$Ra_{t-1}, Rb_{t-1}, Rc_{t-1}, Rp_{t-1},$ $Rs_{t-1}, HRab_{t-1}, HRbc_{t-1}$	$\Delta \theta_t$

where the inputs were normalized according to equations 2 – 19 below. Fundamentally, the inputs for each of the networks were a function of the entity's state at the last simulation clock and how this state related to the road characteristics (width, heading, length of segment, etc) and March Order parameters (speed, end-point, etc). The specific predictors are expressed in 4 – 10, and the parameters making up those inputs are explained in 11 – 19.

$$S_t = S_{t-1} + \Delta S_t \quad (2)$$

$$\text{where } \Delta S_t = f(Ra_{t-1}, Rb_{t-1}, Rc_{t-1}, Rp_{t-1},$$

$$Rs_{t-1}, HRab_{t-1}, HRbc_{t-1}, Hz_{t-1})$$

$$\theta_t = \theta_{t-1} + \Delta\theta_t \quad (3)$$

where $\Delta\theta_t = f(Ra_{t-1}, Rb_{t-1}, Rc_{t-1}, Rp_{t-1}, Rs_{t-1}, HRab_{t-1}, HRbc_{t-1})$

$$Ra_t = S_t / (Da_t + M) \quad (4)$$

$$Rb_t = S_t / (Db_t + M) \quad (5)$$

$$Rc_t = S_t / (Dc_t + M) \quad (6)$$

$$Rp_t = S_t P_t / M \quad (7)$$

$$Rs_t = S_t / M \quad (8)$$

$$HRab_t = Hab_r \times Hxy_t \quad (9)$$

$$HRbc_t = Hbc_r \times Hxy_t \quad (10)$$

$$S_t = \text{entity speed at } t \quad (11)$$

$$Da_t = \text{distance to previous waypoint} \quad (12)$$

$$Db_t = \text{distance to current waypoint} \quad (13)$$

$$Dc_t = \text{distance to next waypoint} \quad (14)$$

$$M = \text{march order speed} \quad (15)$$

$$P_t = \text{perpendicular distance to road} \quad (16)$$

$$Hab_t = \text{direction of road segment ab} \quad (17)$$

$$Hbc_t = \text{direction of road segment bc} \quad (18)$$

$$Hxy_t = \text{entity orientation} \quad (19)$$

Of these, 860 examples were used for training the speed network, 860 examples for training the heading network, and 859 examples were used for validating the training of both of these networks. The training rate was selected as 0.01 and the initial momentum parameter was .9. The momentum parameter was periodically adjusted to speed the rate of descent along the error surface. The training and validation results for each of the networks may be seen in Table 2.

Table 2. Training and Validation Errors

	Delta Speed ΔS Error(m/s)	Delta Heading $\Delta \theta$ Error(rads)
Training	0.259977±2.04558	0.004578±0.00781
Validation	0.206374±0.82532	0.014221±0.06766

Experimental Results

The neural network models were implemented in such a way that their performance for predicting entity location could be compared with the dead-reckoning model. This implementation is presented in Figure 5.

There are two ways of generating an error in our system. The first is according to the entity's location. This error is measured in terms of comparing the entity's dead-reckoned XYZ with the entity's true XYZ and is proportioned according to the width of the entity along its X, Y, and Z axes. For example, an M1A2 tank is 3.56m in width (defined along X-axis of tank), 7.34m in length (defined along Y-axis of tank), and 2.33m in height (defined along

Z-axis of tank). A typical threshold for dead-reckoning error tolerance in DIS is 10% of the vehicle's dimensions. In this case then, the error tolerance for this entity's location would translate into .356m along the X-axis, .734m along the Y-axis of the tank, and .233m along the Z-axis of the tank.

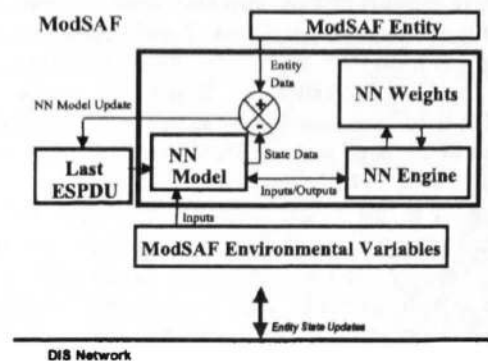

Figure 5. Neural Network Implementation used for Experiments in ModSAF

The second way of determining an update threshold is with respect to the orientation of the vehicle. In this case, the components of the dead-reckoned euler angles are compared with the components of the entity's true orientation. For tracked ground entities in ModSAF, this measure is defaulted at 3°. That is, if the dead-reckoned prediction is more than 3° off about X-axis, Y-axis, or Z-axis, an error is generated. Overall, at these error tolerances, the number of updates (ESPDU's) required by the dead-reckoning model was 351. Using these same error thresholds, the neural network models required 263 updates. Thus, the neural networks required 25% fewer updates than the dead-reckoning models. This information is presented in Figure 6 according to type of update. In the DR case, a small number of the required updates occurred simultaneously between location and rotation.

Figure 6: Number of Updates Required by DR Model versus NN Model

Although the neural network based model was able to predict the entity's path with more accuracy, as evidenced in Table 3, this increase in predictive utility comes at a cost in processing time.

Table 3. Execution Time Using Neural Networks and Dead-Reckoning Equations

	Processing Time (in 10^{-5} seconds)			
	NN Speed	NN Heading	Total NN	DR
Min	6.89029	6.19888	13.08981	2.2888
Mean	7.77692	7.47008	15.24700	2.7974
Max	20.5993	29.7999	50.3992	6.35981

Using the UNIX "gettimeofday" function, the processing speed was calculated on a Pentium III, 500 Mhz machine, running RedHat Linux 6.2. As shown in Table 3, the neural network based model required, on average, about 6 times more processing time than did the dead-reckoning based model. As stated in Section 2, the simulation time was approximately 15 minutes. On average then, the dead reckoning model produced about 23 updates per minute or rather, 1 update every 2.5 seconds (at a threshold of .356m in the X direction and .734m in the Y direction). Alternatively, the neural network based model required about 17 updates per minute, or approximately 1 update every 3.5 seconds (at the same thresholds). Coupling this information with the information on processing time tradeoffs, it becomes clear that for applications where processing time is at a premium, the use of dead reckoning-models may be preferred, in spite of their poorer predictive performance.

To further examine the relationship between the predictive power of the dead-reckoning models and this set of neural network models, we conducted experiments over a range of error tolerances. So, whereas the initial results, reported in Figure 6, were measured according to DIS default values for a tank entity (i.e., .356m, .734m, and 3°), follow-on tests incremented these error thresholds by those exact amounts. Results are presented in Table 4 and reported only by total number of required updates.

Table 4. Updates Required Over Increasing Error Thresholds

Factor of	Error Threshold			Updates Required	
	X-axis (m)	Y-axis (m)	All-axes (deg)	NN	DR
1	.356	.734	3	263	351
2	.712	1.468	6	193	237
3	1.068	2.202	9	157	188
4	1.424	2.936	12	138	156

5	1.78	3.67	15	119	137
7	2.492	5.138	21	98	109
9	3.204	6.806	27	88	92
11	3.916	8.074	33	70	79
13	4.628	9.542	39	69	75
15	5.34	11.01	45	62	73
20	7.12	14.68	60	51	60
25	8.9	18.35	75	48	55
30	10.68	22.02	90	44	48

As evidenced in Table 4, as the error tolerance increases, the predictive advantage that neural networks have over dead-reckoning models becomes less significant for this modeling task.

Summary and Conclusions

As one might expect, the choice of tool must be driven by the modeling constraints. The results reported above suggest heuristics for when to apply which modeling technique. For example, in an application where processing time is not the primary constraint e.g., multi-agent systems communicating over a wireless network, then the increased processing costs incurred from using a neural network may be defensible. Alternatively, in an application where processing time is a limiting factor, then dead-reckoning models may be the more prudent approach. It is interesting to note, also, that the differences in predictive utility of the two modeling approaches becomes less prominent as the error threshold is increased. This speaks to the power of dead-reckoning models to generalize and scale.

It is important to recognize, of course, that the modeling task in this research is limited in scope. Also, a different neural network could have yielded different results. We can not claim that this is the best network architecture or configuration for this specific modeling task. We can only claim that it was one of the more promising configurations with which we experimented. Other configurations may be better. One approach Henninger et al (1999) found particularly effective in improving the neural network based model's performance was to work with modularized models. This approach has been advocated in the control literature (Murray-Smith and Johansen, 1997; Narendra et al, 1995) and robotics literature (Brooks, 1986), and we have started exploring this approach. One of the benefits of adopting this approach is the ability to mix different modeling techniques as they best apply to the problem locally. For example, combinations of architectures and/or algorithms that can be applied to individual sub-problems, make it possible to exploit specialist capabilities. In the problem discussed in this paper, one interesting test would be to use dead-reckoning algorithms in straight parts of the road data base and then use neural networks to guide the turn, as this appears to be where the majority of updates are required.

Abstract

An aptitude for the detection of bilateral symmetry is a fairly prominent aspect of the human visual system. Knowledge of the reasons behind this facility is not so well established, however. Some of the behavioral data indicates that processing of symmetric and non-symmetric stimuli is undertaken in two wholly different manners (i.e. *serial* versus *parallel*). However, the interpretation of this as being due to high level cognitive preferences does not exhaust the list of possible explanations. Using a split-neural network model, we show that instead of cognitive preferences, gross morphological factors may play a large role in underwriting the ability to detect symmetry as a special case of shape perception. The earlier model is consistent with behavioral data, but Occam's razor suggests that we might prefer the newer morphological explanation.

Introduction

Bi-lateral symmetry is ubiquitous in nature. Such symmetry is related to biological morphology, fitness, and behavior throughout the animal kingdom (Dakin and Herbert, 1998). Thus it is not surprising that it has also been shown to be a highly salient property of the human visual system, implicated in many phenomena.

Symmetry is both a morphological characteristic and a perceptual benchmark. From recognition of a suitable mate to apprehension of a possible predator, symmetry plays an important role, being a "non-accidental" property. That is, it is unlikely that symmetry inheres in an image by chance, or when the actual image source is asymmetric. And although increasingly there is the view that symmetry detection is not only universal, but also fundamental, emerging from very low level simple processes (Dakin and Herbert, 1998; Sally & Gurnsey, 2001), there is not yet consensus about the mechanisms that underlie the facility. On the one hand, it seems that symmetry detection is a bottom-up effect of low-level filtering in early stages of the visual process. On the other, it appears to be a top-down preference for image distillation based on its exploitability for segmentation and part decomposition (Baylis & Driver, 1994; Latecki & Lakämper, 1999). Its utility in segmentation applications has caused some to

Figure 1: A familiar optical illusion whose interpretation may depend on the part-decomposition facilitated by symmetry.

comment that "the link between symmetry and segmentation curiously seems to be more than a coincidence" (ven Tonder & Ejima, 2000).

Indeed, the benefit of symmetry detection for segmentation helps promote the view that it is a worthwhile thing to be good at, for segmentation is linked to part-decomposition, which in turn could be key to figure ground separation, even aiding, for example, the interchange foreground and background in a very common visual illusion (Figure 1).

This paper deals with the specific area of contour symmetry, and its effects on human visual processing, by looking at a computational model of a specific behavioral study by Baylis and Driver (1994). The field of behavioral studies on symmetry is large; it often concerns not only contour symmetry, but internal symmetry (Hicks & Monaghan, 2001) and the effects of various filtering processes. For the purposes of this paper, however, we focus on providing a computational explanation for the differences which arise in processing symmetric and repeated shapes, as seen in Figure 2.

Behavioral Studies

Part-decomposition offers a motivation for the "symmetry is special" theory, but alone it says little about the mechanisms involved. Baylis and Driver

Figure 2: Stimuli: symmetric (left) and repeated (right) contours, both showing 8 discontinuities (steps) along the sides.

performed two experiments linking the perception of different shape types to distinctions in cognitive processes. In particular, the experiments aimed to elucidate the relationship between the perception of symmetry and the class of cognitive processes that are termed “parallel.” In this case, “parallel” would mean that in the detection of symmetry in a two-dimensional figure, the subject *does not* engage in anything akin to a serial point-by-point comparison along the shape’s contour. Baylis and Driver used a selection of perfectly symmetric shapes intermingled with shapes whose contours contained “errors” which meant a deviation from the truly symmetric form along 25% of the contour. Subjects made symmetry judgements while the experimenters varied the number of steps along the side of the shape, between 4, 8 and 16. The experimenters wanted to know whether the reaction time and error rate were significantly dependent on this variation.

It was found that symmetry was generally more quickly identified than asymmetry. This indicated directly that subjects were not involved in point-by-point search, which would always terminate earlier with erroneous examples of symmetry. Furthermore, effects of step number on subject performance were slight, and remained well within the accepted limits that define a process to be parallel.¹ Thus, the hypothesis that detection of symmetry is governed by a process impervious to increases in complexity brought about by a greater number of steps seems supported.

But what if the effects of the symmetric shapes were merely an effect of their potentially constrained nature? It might not be symmetry specifically, but redundancy in general that accounts for this semblance of parallel processing. By conducting an analogous experiment, using repetitive shapes (Fig. 2, right side), it should be possible to confirm or dismiss this confound. After all, repetitive shapes are as redundant as their symmetric counterparts, while exhibiting that redundancy via translation instead of reflection.

¹The exception to this was when the shapes were oriented horizontally, where there was a slight effect of step number for symmetric shapes. We touch on this briefly in the discussion of our own model.

This second experiment found a significant effect for number of steps, consistent with the hypothesis that whatever process is used to judge repetition, it is effected by step count, as though it *were* a serial process. This suggests that the main difference between the two types of shapes is that in the processing of symmetry the number of discontinuities along the contour is not a significant factor, while for repeated shapes it certainly is.

Given that repetition and symmetry are equally redundant, it is clear that there must be a qualitative difference between them. The step number effect indicates a point-by-point comparison—a serial search—in the detection of repetition, which is absent from symmetry detection. But a new question arises: what is it that promotes this fast-track route for the detection of symmetry? Beneath the ‘higher-level’ concepts of parallel and serial processing, is there a more fundamental explanation for the fact that symmetry appears to render insignificant the relative complexity of a shape?

Modeling

This paper aims to show that this may be the case and, furthermore, that this could just as equally be the result of gross morphological aspects of anatomy as of high-level cognitive preferences. More precisely, the original assessment of the behavioral data says little about the hypothesis that what is parallel about symmetry perception is actually the ‘ready-state’ of the human processor to accommodate vertical symmetry.

To show this we employ a split neural network, which has previously been used as a rough correlate of the split in human visual processing, modeling reading (Shillcock & Monaghan, 2001) as well as the apprehension of the effects of symmetry in word-based stimuli (Hicks & Monaghan, 2001).

Variations in the typical architecture of neural nets often involve adding one or a number of hidden layers, vertically (Elman, 1993), or the insertion of recurrent connections. Our model employs a specific manipulation of network architecture that is not so common. Instead of devoting the entire hidden layer to the whole task upon which the network is being trained, the hidden layer can be split laterally, with each resulting half being privy to only half of the input (Shillcock et al, 2001). This split affects network performance, as shown in other modeling work. Here we apply it to the detection of symmetry in pseudo-random-block shapes.

Materials and Methods

A series of simulated neural networks, employing a back-propagation learning algorithm, were trained using sets of two-dimensional pseudo-random block shapes represented by patterns of activation. The shapes were presented to the networks through a

Figure 3: The split architecture network reproduces the form presented at the input, which may appear anywhere across the two visual hemi-fields.

shift invariant identity mapping (SIIM) task, maintaining the predetermined 2D block-shape of the stimuli, while moving it sequentially along the input window (Figure 3). Input nodes that fall outside the location of the block have activation zero. The vertical split in the input reflects that of the fovea and thus, as a block is repeatedly presented to the network from all possible positions across the input, it crosses from one "visual hemifield" to the other, activation being redirected to the associated hidden layer accordingly. The network is trained to recognize (represent) the shape it is being trained on.

Each stimulus set contained 60 pseudo-random block shapes, of one shape-type either all symmetric or all repetitive. For each shape type, there were three stimulus sets, with shapes having 4, 8 or 16 discontinuities along the contour (shapes with 8 discontinuities are shown in figure 2). A third class of stimulus, consisting of mixed sets, where the number of discontinuities was homogeneous, but both symmetric and repetitive shapes were represented equally, was also used in training. Due to the presentation of each pattern in all visual input positions, each stimulus accounts for 17 events in the total training set, for a total of 1020 presentation-recognition events per epoch.

After training to a predetermined number of network epochs, each net was tested with novel stimuli. The test set we focus on for the purposes of this paper contained novel blocks that were neither symmetric, nor repetitive. We were interested in seeing how the networks tended towards reproducing the type of shape they were trained on when being presented with these "random" stimuli. The metric used for gauging network performance on these test

Figure 4: The compared "form" produced by trained networks, as a function of step number, under the random stimulus.

sets is discussed in the next section.

For all simulations the PDP++ Neural Nets software from CMU was used, running on an Ultra 5 workstation.

Results

In examining network performance on the two dimensional stimuli, we want a way of gauging the degree to which the activation at the network's output tends generally toward a given type of shape. Fortunately, the stimuli were strictly formal, in the sense that they can be defined in terms of a simple additive exemplar based function. A measure for symmetry measure is based on cancellation around the proposed axis of symmetry, while that for repetition measure but requires that activation add to a constant along arrays orthogonal to the axis of repetition (the bars that constitute the repetitive patterns are of constant length). We adopt a method of summing activations at the output so that the closer we get to the ideals, the smaller this quantity is (i.e. perfect symmetry, like perfect repetition, in the output has a form measure of zero).

Measuring form at the output

A form measure is thus available for each test shape presented to the network. I.e., for the net trained on symmetry and the test set of random (neither symmetric nor repetitive) shapes, there were 20 different weight sets for the trained net, and 20 shapes to test, giving 400 shape-weight combinations. For each we can measure both the symmetry and the repetition of the shape generated by the net's output. Note that we are not concerned with the actual error involved, but with these measures that are based on the activation levels at the output.

Thus the "on-form" measure for a net shows the tendency of its output to resemble the general shape

type with which it was trained,² with smaller quantities indicating greater affinity for that shape type. "Off-form" measures are also available (symmetry in the net trained on repetition, repetition in the net trained on symmetry) and were surprisingly important.

"On-Form" Measure

The general effect obtained in the model is striking. For the analysis described above, we find a significant interaction between shape type and step count when looking at the networks with respect to the type of stimulus used for training. This interaction can easily be perceived in the graphs through the much higher variance in the case of networks trained on repeated shapes (filled bars). Figure 4 shows the "on-form" analysis for the random test stimuli, comparing the degree of symmetry present in the symmetric nets, with the degree of repetition in the repetitive net. The interaction is highly significant: $F(2, 114) = 52.253, p < .001$.

This significant interaction between shape type and number of steps when we are using the measure appropriate for each network tells us one of two things. Either the networks, otherwise identical, have been differentially sensitized to step number by virtue of the type of shape they were trained on, or the manner in which activation is measured dictates that the quantity "tendency-toward-repetition" present in the output of the net will vary more than the quantity "tendency-toward-symmetry," under the regime chosen to gauge it.

"Off-Form" Measure

We can clarify which of these is correct by examining the "off-form" measures. By looking at the output of the symmetrically trained net with "repetition goggles" and repetitively trained net with "symmetry goggles," hopefully we can rule out the confound of this being a measurement effect.

In figure 5 a significant effect does obtain for the "off-form" measures of the random test stimuli ($F(2, 114) = 9.417, p < .001$). However, once more this is in the direction of repetitive nets showing more variance (by a factor of 2, upon examination of means). If the variance was due to the measurement of "tendency-to-repetition," thus leading to a Type I error, we would now expect to see that variance in the symmetric when we are measuring it for its "tendency-to-repetition." For the net trained on repetition, the "off-form" measure shows how symmetric its output is. The sustained effect in the net suggests a general sensitivity to step number,

²I.e. symmetric for the network trained on symmetry and repetition for the network trained on repeated shapes

Figure 5: The compared "off-form" measures produced by trained networks, as a function of step number, under the *random* stimulus.

present even when we are examining how symmetric its output is.

Discussion

The findings of the behavioral experiment were three fold, viz.

- the processing of shapes by the human observer varies qualitatively in accordance with the characteristics of shape's contours.
- the processing of symmetric shapes is carried out in parallel, while the processing of repetitive shapes remains a serial task, with point by point comparisons
- this is ecologically consistent with a cognitive facility that maximized correct figure ground segregation in a two dimensional image

The second of these points was behind the susceptibility to changes in step number on the contours of repetitive shapes only. Their data was consistent with the hypothesis, that processing of repetitive shapes is affected by the cognitive costs associated with serial processing, unlike the processing of symmetric shapes.

In our model, there is a similar distinction in the way the network handles these two classes of stimuli. In particular, when considering the degree to which the specific regularity of shape-type is learned in the network, we find generally better performance on symmetries, in contrast with repeated shapes. In addition, the performance of the nets trained on repetitive stimuli shows that they are affected by the number of discontinuities along the side of the pseudo-random block shapes. This is true for novel stimuli of the same type as well as for non-symmetric, non-repetitive block stimuli.

Interpretations: Step Number

The main effect that we would like to address here is the differential processing of symmetry and repetition by both human subjects and the split architecture.³ The central finding was that there was a strong interaction between shape type and step number, with the repetitive shapes taking the brunt of the effect, far outstripping the variance induced by step number in their symmetric counterparts.

It certainly seems plausible that that difference is based on fixed anatomical features; looking for the features held in common by both the model and the human subjects, the general split in the architecture of the processor is the obvious front-runner. This anatomical consideration in particular suggests how the differentiation of symmetry and repetition may be linked to the distinction between parallel and serial processing *through* the very structure of the processor.

The formalization of what constitutes repetition and symmetry in the block-shapes, activation across the vertical access summing to a constant in the former and having a net difference of zero in the latter, was crucial to the analysis presented here. But it goes further: it implies that for a split processor, symmetry is as simple as cross-checking (or cross-generating, in the case of this task) the output from each hidden layer. Repetition, on the other hand, involves a cumbersome re-calibration, for *every* segment of the repeated pattern, because the cross-image portion of the output is not a simple reflection.

Now if this difference is that symmetrical shapes can be checked by a parallel system, then it is conceivable that that system is rooted in the recognized image being split centrally along its axis of symmetry and each half being presented to each visual cortex, which in turn provides a massively parallel "cancellation" style verification of the image. Were we to assume homotopic and inhibitory commissures, symmetry would be exactly the reciprocal cancellation of activity across the two sides of the visual cortex, an idea that finds little favor in some circles (Dakin, 1998), but which a simple model such as the one here might help to refine.

But how does this explanation differ from that drawn in the original experiment? Baylis and Driver identified an aspect of shape processing in which symmetry was distinguished from repetition by rendering null the processing costs of increased shape complexity. This was elaborated as being a case of parallel versus serial processing, in which complexity, which is directly proportional to step number along the contour, only retarded the serial process,

leaving the parallel process (the detection of symmetry) unhindered. Thus, the process of recognition is essentially one that involves the comparison of the segment end-points that make up the shape, and in the case of symmetry these comparisons take place simultaneously.

In some sense, the model is not incompatible with the take on the behavioral data. Indeed, the human study leaves open the question of what the facilitating mechanism is for the parallel treatment of symmetry, and the model provides one such possibility. Nevertheless, there is an important contrast. As discussed below, the notion of what constitutes complexity is not fixed. For Baylis and Driver, complexity increased with step number, and parallel processing was where such an increase was insignificant. For the model however, it would be quite an assumption to simply associate increased step number with increased complexity, for point-by-point comparisons of the stimuli have little meaning in a model lacking a temporal dimension. However, the difference between the symmetric and repetitive shapes is just as marked. In the absence of any sequential processing, this indicates that symmetry is special not in avoiding the narrow view of complexity-as-quantity, but in generally "playing-down" any dependence on contour variations. Since parallelism and seriality have no temporal meaning in the model there must be a more fundamental retreat from complexity that symmetry offers.

Complexity

Above, we alluded to the unfixed nature of complexity. A potential shortcoming in the modeling result is that the effect of step number seems to manifest in the reverse direction. That is, an increase in the number of steps in the stimuli presented to nets trained on repetitive shapes meant an increase in how well that nets output stayed to form (form in this case being repetitive). We would expect this "accuracy" to decrease, given that more steps presumably means greater complexity and therefore a harder task (and one for which, in the original experiment, the authors saw a need for more "counting" time). If anything, the results of the model disturb the clear relation obtaining between the original interpretation of serial versus parallel and how each accommodates effective increases in complexity.

Of course, there is no claim that the model attempts to perform either serial, or parallel processing, in the sense that Baylis and Driver use those terms. And it is hoped that the previous section went some way to reducing the high-level cognitive connotations of these terms to more concrete, anatomically based concerns. The networks learn to perform an identification task, and in doing so they pick up the general trends elicited by the stimuli sets used for training. It is in this sense then that processing of shape type differs: it will depend on how

³Though beyond the limits of this paper, it is worth noting that an effect of orientation found in the behavioral study, marked generally by poorer performance (RT and error), also falls out of the split-network model.

the task was learned in the first place.

In this context let us ask what complexity is. For though an increase in complexity can be equated with an increase in step number; for our model it won't be. Again, complexity in terms of the number of sequential operations performed (i.e. counting the steps) has no meaning in the context of the network. So how could a contour with 16 steps appear easier to process, or be in general more likely to encourage good "on-form" output, than one with only 8 or 4 discontinuities?

The answer to this involves reviewing the nature of the task, from the network's perspective: to reproduce accurately a contour of maximal discontinuity, which, in the case of this model, is one with 16 steps, the net at least has the advantage of avoiding any cross-row constraints. That is, given that the grain of the image and the grain of the shape in question match, no additional provisos are required in order for the net to attempt reproduction of the input at the output. Thus the task is relatively unencumbered, and the result is a more stable version of the form learned during training. But reduce the number of steps along the contour and the complexity of the task the net has to solve is actually *increased* by virtue of the added constraints of aligning rows of "pixels" at the output.

It isn't that this in itself disrupts the measure of form at the output, for that is always measured at the grain of the model, but that such additional constraints divert the resources that the net has devoted to producing well-formed images. The result is a drop in the form at the output, but, and this is the key point, this whole story, in which complexity for the network is revealed to be the opposite of what one would expect, only effects repetitive shapes.

Summary

The described model presents interesting analogues to some of the main effects uncovered in behavioral studies. In particular we have the preference for the processing of symmetric shapes, which is much less susceptible to variations along the contour than is the processing of repetitive shapes.

As already noted, symmetry may initially seem more complex a phenomenon, in terms of the operations required to generate symmetric contours (translation and reflection). However, from an anatomical perspective it may in fact be simpler, especially around the vertical axis. This relates to the view that homotopicality between the visual cortices promotes the recognition of vertically oriented symmetry—because information, instead of being quantized and stored, can be "mirrored and checked" directly.

Baylis and Driver present a plausible argument for symmetry preferences in terms of parallel and serial processing, in the cognitive sense. However, more parsimonious explanations may be available. Using

a split architecture neural net, we have suggested that the symmetry preference may arise from gross anatomical aspects of the processor. If this is so, then the application of Occam's Razor suggests that there is a simpler story on symmetry.

Perspective-taking in Young Writer's Descriptive Writing

David R. Holliway (holliway@marshall.edu)

Department of Educational Foundations and Technology, 122 Jenkins Hall, Marshall University,
400 Hall Greer Blvd.,
Huntington, WV 25755 USA

Abstract

This paper reports a perspective-taking strategy that assisted younger writers in representing the descriptive needs of their readers. There were 154 writers (78 5th-graders and 76 9th-graders) and 52 9th-grade readers that participated in the study. Three conditions were contrasted: a feedback only condition, a "rating other" condition, and a "reading-as-the-reader" condition. Readers' correct description-to-tangram matches made for each of three sessions served as the dependent measure. Repeated measures analysis revealed both the 9th- and the 5th-grade writers showed consistent significant improvement under the "read-as-the-reader" condition when revising their essays and when drafting anew. The results suggest that when young writers engage in a process that mirrors their readers' experiences, they can more accurately revise their descriptive writing to meet their readers' informational needs.

Theoretical perspective

Writing is simultaneously an individual struggle and a social undertaking (Dyson & Freedman, 1991; Fitzgerald, 1992; Florio, 1979; Flower, 1994). Writers face the individual cognitive task of selecting what information to communicate and how they will communicate it. Inseparably, writers consider who their readers will be and the context of their reading. Writing scholars (Traxler & Gernsbacher, 1992, 1993; Fitzgerald, 1992) theorize that to meet the informational needs of readers, a writer must coordinate at least three interacting mental representations: a representation of personal communicative intent (what do I want to say?), a representation of the text produced (what have I written?), and a representation of the reader's perspective (how will the reader interpret my writing?).

Establishing reciprocity between reader, writer, and text is the hallmark of experienced writing (Witte, 1992; Olson, 1994). Considerable research (e.g., Bereiter & Scardamalia, 1987; Beal, 1996) has demonstrated that young writers are particularly challenged in learning this writer-reader-text reciprocity. Specific instructional conditions that foster "comprehension monitoring" (Beal, 1996; Fitzgerald &

Markham, 1987) and "knowledge-transforming" (Bereiter & Scardamalia, 1987) can help young writers discriminate their intended message from the actual text they have composed, thus influencing *the textual quality* of their writing. Fewer studies, however, have outlined conditions that may help improve younger writers' awareness of their readers' possible interpretations. For example, Frank (1992) found that subtle manipulation of "audience specification" in writing prompts led fifth-grade writers to compose their newspaper advertisements differently for two separate audiences. The research literature (e.g., Bonk, 1990) remains unclear about instructional conditions that can help young writers view their text from the perspective of their readers, and thus improve *the communicative quality* of their writing.

To investigate how older students might become more sensitive to their readers' needs, Traxler and Gernsbacher (1992, 1993) asked college students to compose and revise descriptions of tangrams for anonymous readers. The readers' task was to read each description and then select the matching tangram from a group of similar-looking tangrams. The writers who went through a revision process identical to that of their readers consistently wrote the most effective texts. Traxler and Gernsbacher (1993) concluded that the reciprocity between readers' needs, text, and writer could be successfully accomplished when writers read-as-their-readers, that is, when writers learn to take the informational perspective of their readers. If consideration of the readers' needs is critical to "good thinking during composition" (Fitzgerald, 1992, p. 345), then "reading-as-the-reader" may enable young writers to consider the descriptive needs of their readers. Reading-as-the-reader may be one strategy whereby young writers can coordinate "what do I want to say?" and "what have I written?" with "how will the reader interpret my writing?"

This paper reports on-going research (Holliway, 2000; Holliway & McCutchen, in press) that suggests "reading-as-the-reader" can improve fifth- and ninth-grade writers' ability to compose descriptive writing consistent with their readers' informational needs. Three questions guide the present paper: 1) Can "reading-as-the-reader" assist young writers in composing and revising descriptive writing that meets their readers'

informational needs? 2) What do the writers' post-experiment reflections reveal about three contrasting perspective-taking conditions? 3) How are the "readers' informational needs" reflected in the descriptive strategies used by these writers?

Methods

Participants

All participants came from four elementary schools and three high schools located in a large metropolitan area. There were 154 writers (78 5th-graders and 76 9th-graders) that came from regular language arts classes. The readers were a separate group of 52 9th-grade readers in advanced placement English classes.

Design

A written referential communicative paradigm was adapted from Traxler and Gernsbacher (1993). The writer communicated the details of Tangram to a reader who chose the "target-gram" from a group of similar-looking tangrams. There were three writing sessions each separated by one-week intervals. Each writing session was followed on a separate day of the same week by a reading session.

Materials

The tangrams that the writers described came from a collection of 72 figures (similar to those used by Traxler and Gernsbacher, 1992, 1993; Clark and Wilkes-Gibbs, 1986). Tangrams were counterbalanced across sessions and conditions.

Procedures for Writers

Session one

All writers were given a notebook with three tangram figures to be described. Writers had 30 – 35 minutes to complete their descriptions.

Session two

Writers in each classroom were randomly assigned to one of three perspective-taking conditions. The three conditions differed in how closely the writers' task mirrored that of their readers.

Feedback-only condition

Writers received a sentence for each description indicating whether their reader had successfully matched the description with the associated target-gram. Writers then revised their original descriptions.

Feedback + rating-other condition

Writers received a feedback sentence for each description indicating whether their reader had successfully matched the description with the associated target-gram, plus three descriptions written by another student. Writers rated the descriptions by considering the informational adequacy of each description (e.g., which

description creates a clearer picture in your mind?). After finishing they revised their original descriptions.

Feedback + reading-as-the-reader condition

Writers received a feedback sentence for each description indicating whether their reader had successfully matched the description with the associated target-gram, plus three descriptions written by another student, and then they matched each description with tangrams, exactly as their readers had done. After they finished their matching, they revised their original descriptions.

Session three

After finishing their task-specific activity, all writers received a new set of three tangrams to describe.

Procedures for Readers

The readers received a notebook that contained typed versions of the tangram descriptions, and a scorebook wherein they made their description-to-targetgram matches. For the entirety of the experiment, the same reader scored the same three writers, each writer representing one of the three experimental conditions.

Results

Quantitative analysis

The dependent measure for the 2 (grades) x 3 (tasks) x 3 (sessions) repeated measures analysis was the number of correct description-to-"target-gram" matches that each reader made for each description they read (For Mean differences see Table 1 below).

Table 1: Means and standard deviations by Session, condition, and grade.

Condition	Session 1			Session 2			Session 3		
	N	M	SD	N	M	SD	N	M	SD
Feedback									
9 th -grade	18	2.17	.92	18	2.39	.85	18	2.28	.96
5 th -grade	25	1.80	.76	25	2.20	.76	25	1.68	.95
Rate-Other									
9 th -grade	26	2.23	.77	26	2.42	.76	26	2.42	.70
5 th -grade	30	1.87	1.04	30	2.00	.95	30	2.27	.87
Read-as-the-Reader									
9 th -grade	32	1.75	.88	32	2.25	.84	32	2.47	.67
5 th -grade	23	1.57	.59	23	2.13	1.01	23	2.26	.69

The between subject effect revealed a main effect of Writer, $F(1,148)=11.00$, $p=.001$. On average, the ninth-graders scored higher than the fifth-graders throughout all sessions and in all tasks. The within subjects effects revealed a significant main effect of Session, $F(2,296)=8.76$, $p<.001$, with session 1 ($M = 1.88$, $SD =$

86) yielding fewer matches than session 2 ($M = 2.22$, $SD = .87$) and session 3 ($M = 2.24$, $SD = .83$). However, the session main effect was compromised by a significant interaction between session and condition, $F(4,296) = 2.96$, $p = .019$. Post hoc analyses (Tukey's Honestly Significant Difference (HSD) approach) established that differences between session 1 and sessions 2 and 3 were significant only for the read-as-the-reader group (critical value = .375, $p = .05$). No other interactions reached significance ($F < 1$). These results suggest that reading-as-the-reader helped both the 4th and the 9th graders in meeting their readers' informational needs more than the other two conditions.

Qualitative analysis

An analysis of the writers' open-ended free-writes about their "reading-as-the-reader" experiences revealed that the task was very useful for these writers. Students portrayed their writing experiences on a variety of levels, usually characterizing the task in some way as fun or boring, insightful or uninspiring. The student free-write responses were used to generate a general coding scheme that categorized their experiences as positive or negative, useful or not useful.

Based on the coding scheme, the percentage of students in each condition who characterized their writing experience positively was calculated. Not all students provided a free-write. Table 2 presents the number of students responding in each condition, as well as the percentage. The percentage of positive responses from students in the Feedback condition was compared to those in the Rate-Other and the Read-as-Reader conditions. Students in the Feedback condition were significantly less likely to characterize their writing experiences as positive, compared with students in the other two groups (Fisher's Exact = 6.787, $p = .005$).

Table 2: Actual number and percentage of students who responded positively to their experimental condition.

	Positive Response	
	# Responding in each condition	% Who responded from each condition
Feedback	20	46.5%
Rate-Other	38	67.9%
Read-as-Reader	39	70.9%

To investigate the "readers' needs" a profile was compiled based on the readers' open-ended comments made at the end of each reading session. An analysis of

their comments about what they needed from their writers revealed that a *global conceptual image* created by an analogy with a balance of *local shape and spatial elaborations* helped them discriminate and chose the "target-gram" from the group of similar-looking tangrams. For example, one reader commented: "The descriptions that were the best were very detailed in the shapes and what the figure looks like it's doing." The readers' profile revealed that the readers' informational needs were met more efficiently by writers who elaborated on the analogical referent with a balance of shape names (e.g., triangle, parallelogram, square), geometrical qualifications (e.g., zigzaggy, diagonal, pointy) and location descriptors (e.g., to the right, on its left, the left one).

A text analysis of the descriptions revealed that many writers, regardless of condition and grade, began their descriptions with analogies (e.g., "It looks like a running fox," "This tangram looks like a ghost flying.") These "spontaneous analogies" (English, 1997, p. 15) may be one way writers are attempting to establish a common perceptual ground with their readers. Writers varied, however, in the way they elaborated on the spatial and geometric qualities of the tangrams they described. Many writers used an "object centered" strategy that focused on the intrinsic details of each tangram. For example this writer's description represents a common strategy: "It looks like a goose. It has a long zigzagging neck. It has a small head and a pointed beak. Its body is kinda [sic] long and it has two feet on top of each other." At this point in the analysis it is not easy to identify changes in writing strategies and textual features due to enhanced reader perspective. Initial text analyses of the descriptive essays generated in this study reveal few structural differences that can be associated with condition.

Discussion

Theoretical Implications

All three groups of writers received feedback indicating the accuracy of their reader's choice. The rate-other group also read and evaluated descriptive tangram texts written by other students. However, only the read-as-the-reader group was asked to take their readers' perspective in the actual task of matching descriptions to tangrams. Although the mean scores improved significantly from session 1 to session 2, the cognitive potency of the read-as-the-reader condition emerged most strikingly in the "transfer comparison" between sessions 1 and 3. It may be the case that the intervention duration was not sufficient in the second session to show a significant revision in the original descriptions. Perhaps more than one experience with reading-as-the-reader is necessary for younger writers to show the benefits.

An alternative explanation involves the nature of the writing task in session 3 compared to session 2. In the second session (revision session), writers may have been under the influence of the text they had already created; the actual physical text that they composed in the first session may have constrained the creation of a new text fresh with detail. Bereiter and Scardamalia (1987) suggest, "the original version of text, *because it is perceptually present* [emphasis added], has a direct claim on conscious attention. Unless the writer can deliberately bring alternatives to mind, the original text will win for lack of competition" (p. 87). The reading-as-the-reader condition had the greatest impact when students were given a chance to apply and recontextualize what they had learned from composing one set of texts to the composition of a similar, but new texts. That is, when writers drafted anew in the third session, unconstrained by an existing less-effective text, they were able to demonstrate what they had learned from "reading-as-the-reader."

The positive responses that students made suggests that "reading-as-the-reader" gave these writers a perspective on the effects of their writing that they otherwise might not have considered. One writer reflected "I like to read other kids' descriptions because sometimes if I read other kids [sic] descriptions I can get more ideas . . . because when I look back into the pictures I can't see the pictures they see." The analysis of the writer's comments from the read-as-the-reader group suggests that actually doing the task their readers did revealed to them the necessary information they needed to include and the unnecessary information they needed to exclude in their descriptions.

Further research might "directly probe the ways in which individuals cope with the items or task, in an effort to illuminate the processes that underlay item response and task performance" (Messick, 1989, p. 6). By conducting protocol analysis students' thoughts could be assessed to reveal the kinds of decisions that writers make and the kinds of information they chose to include and exclude, and ultimately, the kinds of discourse strategies that they chose to use in an attempt to meet their readers' informational needs. This is one approach we might take to better understand how reading-as-the-reader can assist younger writers in accomplishing the writer-reader-text reciprocity.

Educational Implications

This research contributes to a body of literature (e.g., Beal, 1996; Cameron, Hunt, & Linton, 1996; Frank, 1992; Oliver, 1995) that clarifies some of the instructional conditions that can help young writers envision how their readers' interpret the text they have written. Specifically, it contributes to our understanding of how younger writers can learn of the reciprocity between writing, reading, and text (see Witte, 1992). The

study offers empirical support for the widespread classroom practice of peer editing and peer response. This study suggests, however, that peer response may be more effective when peers actually use the text in some way, because they are forced to confront the text's strengths and weaknesses in a concrete context, rather than the more abstract context of giving literary feedback.

Although the "referential communication design" has been traditionally associated with experimental psychology and spoken communication, similar activities and communicative processes are found in writing instruction literature. For example, an adaptation of the writing/reading exercise "reading-as-the-reader" might be added to a teacher's repertoire of "optimal environmental activities" (Daniles, 1990, pp. 118-121). Daniles suggests, "lessons about effective descriptive writing emerge from experiencing strategies in use" (p. 119). "Reading as the reader" is a perspective-taking strategy experienced when the writer attempts to create a specific description their readers can "see."

Another application of "reading as the reader" would be a perspective-taking strategy that can be added to a "writer's tool box" (Harper, 1997). Harper describes five revision tools that she suggests have worked for her as a practicing middle school writing teacher. One such tool is the "snapshot." Students compose written snapshots similar to a detailed photographic snapshot. Snapshots are writing activities that compel students to concentrate on the physical properties and descriptive qualities of various "objects." "Reading-as-the-reader" could be an instructional tool that writing teachers incorporate into his/her repertoire of classroom activities to help students become more efficient descriptive writers.

Finally, "reading-as-the-reader" may help students to make details explicit and assist students in recognizing other text creating approaches that could be used with other functions of writing. Composing concrete poems and descriptive essays and then "reading as the reader" are classroom experiences that may facilitate students going beyond their immediate personal and social circumstance (Cameron, Hunt, & Linton, 1996; Elsassner & John-Steiner, 1977; Florio, 1979). If "reading-as-the-reader" is a learning strategy that worked for younger writers in helping them develop a readers' perspective in transactional writing, it might also be a strategy transferable to other writing purposes. Not only does "reading-as-the-reader" assist writers in asking, "what do I want to write?" and "what have I written?", more importantly, it may assist in addressing the more challenging task of, "How will the reader interpret my writing?"

Abstract

How do people control interactive search? One type of decision that is made when performing a task such as searching the web is whether to continue to explore unattractive but immediately available links or to backup to previously experienced links. It has recently been suggested that this choice may be governed by a preset threshold. We report empirical evidence that in fact the choice is governed by memory for the quality of the unselected alternatives on previous pages. Further, we report a computational model that combines an instance-based memory for previous evaluations with display-driven action to control interactive search.

Introduction

Tasks such as web browsing and menu search are examples of what we call *interactive search* tasks. They differ from other problem solving tasks in that the effect of an operator is unknown until the operator has been implemented in the world. In these circumstances a problem solver cannot use mental lookahead in order to constrain search, rather search is constrained by two mutually dependent cognitive activities.

First, people estimate the relative likelihoods that operators will lead to the goal and trade these off against estimates of cost (Pirolli and Card, 1999). In interactive search, estimates of likelihood are typically based on an interpretation of the relationship between the goal and the semantics of the word(s) and icon(s) used to represent the operator. Estimates of cost are often based on the time that operators are expected to take to implement in the world.

Second, the process of likelihood estimation must be embedded within a strategy for controlling search. A strategy typically defines policies for determining which operators are included in the set of those considered and policies for reducing or eliminating the probability that operators that have been tried before are redundantly reselected. Typically a strategy for interactive search will be supported by memory for which operators have already been tried on the current search (so that reselection can be avoided) and by memory for information about which operators lead to success or failure on previous trials (Howes, 1994).

Howes and Payne (2001) have argued that these needs are not easily captured by current architectural theories of human cognition.

A search strategy is required in addition to an ability to follow label semantics because in real menus and on real web pages, label semantics (and therefore estimates of likelihood) are rarely sufficient to guarantee that users will navigate directly to the location of a goal without some fruitless exploration of other parts of the search space. An understanding of the process by which people rank order operators must be complemented by a model of which they consider, how they remember which they have tried, and how they remember where to find them.

Previous research on the strategies that people use to control exploration in these circumstances has emphasised that performance is often display-based. I.e. problem solving is constrained by the set of operators currently available on the display of the device (Howes and Young, 1996). The device display imposes constraints on the problem solving process that limit the cognitive costs of device use. Other research has indicated that judgements of what choices have been taken before are sometimes made on the basis of long-term representations of familiarity (Payne, Richardson, Howes, 2000).

Other research has directly addressed the question of when users choose to 'backup' from a choice point. A 'backup' operator is a special kind of operator in interactive search in that the user knows that its effect is to return the user to the previous, higher, node in the tree (although the user may not know the content of this node). There are a number of types of backup in web browsing. The 'Back' button on a browser takes the user to the previous page in the recent history stack. A link labelled 'back' on a web page will typically take a user to a page one level higher in the site hierarchy (though this is not guaranteed). The differences between these operations are potentially interesting but for here we consider a generic backup where the two definitions are aligned.

One answer to the question of when users choose to backup is that backups are selected when evaluations of all available forward moves fall below some threshold (Miller and Remington, 2001). In their model, Miller

and Remington assumed that users selected a link whenever the perceived likelihood of success exceeded some predetermined threshold. They point out that a feature of this model is that it places little demand on memory. Search is controlled without a memory for previous alternatives to the current search path. Miller and Remington also describe an elaboration of their threshold model in which "improbable links at a lower tier" are selected opportunistically. This is achieved by temporarily reducing the threshold for selection. Their model was motivated by examination of web usage logs which suggested that users selected less probable links before backtracking to other possibilities.

An alternative model is that people moderate their willingness to backup according, in part, to their memory for the quality of previously unselected operators at higher levels in the menu tree. In this model a single fixed threshold would not be used, rather backup would be selected according to a computation of the relative values of an extended set of operators that included, but was not limited to, those derived from the currently displayed labels. It is possible that people backup if the previous label was significantly better than the current labels, or perhaps only if both the current labels were below some threshold (as in Miller and Remington's model) and the previous label was above some other threshold.

In addition it seems likely that the perceived time cost of successfully returning to a remembered option will moderate people's willingness to select a backup option. Such behaviour would be consistent with recent findings in Human-Computer Interaction (Gray & Fu, 2001) and with the conflict resolution mechanism of ACT-R (Anderson and Lebiere, 1998).

In this paper we first report an experiment designed to test the hypothesis that when engaged in interactive search tasks people take into account the value and cost of options other than those that are immediately available on the computer display. We also report a model of interactive search, that is consistent with the results of the experiment, and which is based on an instance-based framework of memory for problem solving. The model was developed in response to the current findings and in part to our previous work on

interactive search (Payne, Richardson and Howes, 2000; Howes and Payne, 2001).

Experiment

The aim of the experiment was to test the hypothesis that people take memory for the value and cost of unselected menu options from previous choice points into account when deciding whether to backup. Participants were asked to search for a different target in each of a series of identically structured binary menu trees. Selection of an option resulted in the displayed menu being replaced by a submenu. The trees differed in three respects: (a) the quality of the weaker option at the top level choice-point in the menu (either a good, average or bad choice); (b) the quality of the two options at the lower level, or critical choice-point (either both bad or both very bad choices for the goal); (c) the cost of backup.

The quality of labels was determined by previous studies in which participants were asked to fill in a questionnaire indicating the likelihood that they would select a label for a particular goal. For example, they were asked to rate "Cowboy movies" and "Facts and Figures" for the goal, "find when John Wayne died." Answers were given on a five point scale, from 1 (very likely), to 5 (very unlikely), the levels of which are referred to in this paper as very good, good, average, bad, and very bad.

In accordance with (a) and (b) above, at the top level of the menu tree there was always one very good option and one that was either good, average or bad. On the menu underneath the top level very good option there was a node with labels that had both been rated bad or both very bad. (Of their own volition, participants were expected to mostly select the best choice at the top level.)

The number of times that participants chose to backup as the first move made from the critical choice-point was recorded. The design of the experiment allowed us to determine whether the number of backups was dependent only on the quality of the labels at the critical choice-point (bad vs. very bad) or also on the quality of remembered but untried labels at higher levels of the tree (good vs. average vs. bad) and/or on the cost of backup.

A "give up" option was available so that participants did not need to follow paths under bad or very bad options in order to find the goal. This would otherwise be the case in the menu trees where the alternative option at the first choice-point was a label that had been rated as bad. This was designed to ensure that participants experienced minimal positive feedback for the bad menu labels.

Method

Participants. Thirty-six undergraduate students (30 females and 6 males) participated in this study for course credits. The mean age of participants was 19 years 11 months.

Materials. Twenty-seven binary menu trees were used. Participants were required to find a single goal in each of the menu trees. The goals were all to find general information on different topics.

The twenty-seven menu trees consisted of eighteen test menu trees and nine filler trees. In each tree the first choice was between a label that had previously been rated as a very good label for the goal, and one that had been rated as either good, average or bad. The very good choice led to a choice-point where the two labels had been rated as either both bad or both very bad.

Nine different topics were used for the test trees, with each topic occurring twice. Each topic was used for a menu tree with a very bad critical choice-point and for a menu tree with a bad critical choice-point giving nine of each in total. Within each of these sets of nine menu trees, three had a good alternative option at the first choice-point, three had an average option and three had a bad option. Across participants, each topic was presented equally often as each of the six different types of test menu.

There were two locations for the goal in each of the test menu trees. The goal information could be found either by moving forwards from the critical choice-point, or by backing up from it and searching the other half of the structure.

Procedure. All participants carried out a simple menu search training tasks before taking part in this experiment. After reading the instructions, participants worked through three practice search tasks and then through the twenty-seven menu search tasks presented in a different partially-randomised order for each participant. Presentation of tasks was self-paced in that participants had to find the goal (or give up) before the next task could be started. Selections were automatically recorded by the program.

Participants were randomly assigned to either a low-cost, immediate backup group or to a high-cost, slow backup group. Participants in the high-cost group had to carry out two intermediate steps between clicking on backup and getting to the previous choice-point. Both of these steps required participants to click buttons in windows to confirm that they wanted to backup. As before, participants in these two groups were matched for frequency and length of Internet use.

Results and Discussion

The tendency to select the give-up option rather than continuing until the goal was found was very low. It

was used on only 5% of tasks on average. As expected, it was used most often on those tasks where the untried option at the first choice-point was bad rather than good or average.

The mean percentage of backups made as the first move from the two types of critical choice-point (bad and very bad) in each of the three types of menu tree (good, average or bad untried previous option) was calculated for each participant. These data are summarised in Table 1 and were subjected to an Anova to test for effects of critical choice-point type, preceding untried option type and cost of backup.

Critical choice-point	Previous untried option	Fast backups		Slow backups	
		M	S.D.	M	S.D.
Very bad	Good	73%	31%	55%	37%
Very bad	Average	61%	26%	52%	25%
Very bad	Bad	50%	26%	50%	30%
Bad	Good	70%	28%	61%	26%
Bad	Average	52%	38%	45%	22%
Bad	Bad	44%	30%	44%	25%

Table 1. The mean backups made as the first move from the critical choice-points in each menu type.

There was a significant effect of the goodness of the preceding untried option on the number of backups made, $F(2, 68) = 8.45$, $p < 0.01$. Significantly more backups were made from the critical choice-point when the preceding untried option was good than when it was bad or average. There was no main effect of the quality of labels at the critical choice-point, $F(1, 34) = 1.14$, $p = 0.29$. Equal numbers of backups were made whether the options were bad or very bad. This was not due to floor or ceiling performance: the average percentage of backups made from the critical choice-points was 55%.

There was not a significant main effect of cost of backup, $F(1, 34) = 1.77$, $p = 0.19$, nor were there any significant interactions.

Finally, there are two ways of looking at this data, either in terms of the assessment of the preceding untried option (as above), or in terms of the difference between the untried option and the options at the current choice-point. However, it is hard to quantify differences in assessments. The fact that there was no significant difference between bad and very bad critical choice-points is evidence against the difference in assessments being a factor.

An instance based model

The model is a computationally implemented model of the strategy underlying the direction of the effects observed in the experiment. It consists of an algorithm

implemented in a simple but novel production system framework developed by the authors. A brief description of the framework is given before the details of the strategy.

Framework

The basic assumptions in the framework (though not the model) were motivated by previous research rather than by the current findings. The primary motivation was the problem of discriminating which trial a memory was from, and in particular whether a memory was from the current trial or from a previous trial. Howes and Payne (2001) have argued that the way in which information is represented in ACT-R's declarative memory (Anderson and Lebiere, 1998) makes it difficult to model the control of search over multiple trials within the same search space. One problem is that the combination of frequency and recency information in base level activation makes it difficult to distinguish whether an activation is high because a representation was used on the current trial (recency), or high because it has been used many times before (frequency). While ACT-R models are sometimes built so that they do encode episodic chunks, it is not clear from the theory when a new chunk should be encoded and when the activation of an old chunk should be increased.

The instance-based framework that we describe here is a response to these problems. Where in ACT-R, repeated exposure to a goal or aspect of the environment results in an incremental increase in the base-level activation of the chunk, in the framework described here, repeated exposure to patterns results in the encoding of separate instances (where an instance is a structure consisting of a collection of attribute/value pairs). Effects of frequency can be captured in the framework by a race between instances that match to the current goal and state. The approach has been inspired by Logan's (1988) instance-model of practice and by Altmann and John's (1999) episodic account of how people control search during program comprehension.

In brief, the main assumptions behind the framework are given below. Many of the assumptions are derived from ACT-R and Soar but the framework differs substantially from both in the structure of its declarative/working memory. While we believe that these assumptions have the potential to offer a novel approach to modeling the control of cognitive behavior, they should not be taken in their current form as a competitor to the established architectures. ACT-R for example consists of a sophisticated set of mechanisms that have been shown to be useful in modeling a broad range of behavior. In contrast, we have focused on just those mechanisms required to capture a handful of

experiments on a specific but important issue. The assumptions are:

1. The framework includes two types of data structure: (1) production rules, and (2) instance structures. Production rules match to instance structures to produce more instances and/or action.
2. Instance structures consist of (Identifier, Attribute, Value) triples. So for example, (o1, isa, operator), (o1, name, press), (o1, target, "tools"), (o1, state, s1) represents an operator o1 with four features. Similarly, (s1, isa, state) might be part of the representation of the state to which o1 has been applied. An instance cannot be modified or deleted. New instances may refer back to old instances.
3. The identifier of the most recent instance is held in a buffer. Another buffer holds a specification of the input (information from perception).
4. Whenever a production rule fires it adds new instances to instance memory. So for example, if the production that created o1 was to fire again it might add the triples, (o2, isa, operator), (o2, name, press), (o2, target, "tools"), (o2, state, s5). Both o1 and o2 would then be in instance memory, but note that only o2 would be linked to s5.
5. Conflict resolution. Serial control is imposed at the level of production firing. A production only fires once on the same data. Production matches are selected at random, though behavior may be moderated by high frequency matches.
6. Productions propose operators. Operators can carry preferences, e.g. "high", but are otherwise selected at random after a certain number of cycles have passed since the previous choice.

Unlike in ACT-R, frequency and recency information are not merged and it is not therefore difficult to distinguish the current trial from previous trials. The framework is suitable for modeling the findings of Howes and Payne (2001). It is also suitable for modeling the results of the experiment reported here.

Strategy

The results of the experiment indicate that much of the time participants preferred higher value operators regardless of whether they were available on the current menu. The strategy for the model therefore considered not only choices available on the current display (i.e. those that are cued by the environment) but also choices that it had previously experienced. The strategy was encoded in the instance-based framework in terms of a set of production rules. These rules proposed operators determined by the currently displayed menu items and by instance-based memory for previously displayed untried operators. Importantly, as we will see, the model did not need to remember the previous label, merely the fact that there was a previous highly rated choice.

The experiment was also suggestive of some effect of the cost of backup on participants' decision making. While this effect was not significant, it would be surprising and counter to much previous work if people did not take cost into account in this kind of decision and we have therefore chosen to include a sensitivity to the cost of backup in the model.

Even for this simple experimental task, the production rules also need to be sensitive to whether a memory was from the current trial or from a previous trial. Participants in the experiment experienced a whole sequence of tasks, and would have had to be able to determine whether a memory for a previous, highly rated menu option was for the current task. This is achieved by taking advantage of the discrimination made available by the instance-based encoding.

Behavior of the model

To illustrate the behavior we offer a trace for a typical experimental scenario. The model was given the goal of finding the target "John Wayne". The first choice was between "Films" and "Celebrities" for both of which the model had been given a "high" likelihood rating (based on a collection of human ratings). The model retrieved these ratings (lines 2 and 4) and also asserted that neither label had been recognized as tried for this trial (lines 1 and 3). On the basis of the gathered evidence the model then proposed the selection of each button (lines 5 and 6) and then selected "Celebrities" at random (line 8). (note that "..." indicates where there was a sequence of "wait" operators (e.g. line 7).)

```

1. recognise_no i13 label="Films"
2. retrieve_likelihood i14 label="Films" value=high
3. recognise_no i15 label="Celebrities"
4. retrieve_likelihood i16 label="Celebrities" value=high
5. propose_forward i17 label="Films" pref=high
6. propose_forward i18 label="Celebrities" pref=high
7. ...
8. Select: i18
9. apply_forward i24 ACTION (press "Celebrities")

```

The model was then presented with a choice between "Comedy Films" and "Companies" both of which had been given a "low" rating (lines 10 and 13). Two "low" rated forward operators were then proposed on the basis of the gathered evidence (lines 16 and 17). In addition, a "high" rated alternative was retrieved (line 11). This retrieval was made from a previously encoded instance of a highly rated proposal, but importantly, retrieval for the actual label was not required. The retrieval led to the proposal of a "medium" rated backup operator (line 12). The model chose the backup operator (line 19) over the "low" rated forward operators. NB. backup was only given a "medium" rating in this circumstance because of the additional cost to be expected prior to

the selection of the forward move to which the model was returning.

```

10. retrieve_likelihood i30 label="Comedy Films" value=low
11. retrieve_alternative i31 target=i17 pref=high
12. propose_backup i32 label=backup target=i17
    pref=medium
13. retrieve_likelihood i33 label="Companies" value=low
14. recognise_no i34 label="Comedy Films"
15. recognise_no i35 label="Companies"
16. propose_forward i36 label="Comedy Films" pref=low
17. propose_forward i37 label="Companies" pref=low
18. propose_backup i38 label=backup target=i17
    pref=medium
19. Select: i38
20. apply_backup i40 ACTION (press backup)

```

At this stage the model has returned to the top-level choice point and immediately recognized that it has tried the "Celebrities" label before on this trial (line 21). However, as "Films" is not recognized as tried and is highly rated it selects it (line 27).

```

21. recognise_yes i46 label="Celebrities"
22. retrieve_likelihood i47 label="Films" value=high
23. recognise_no i48 label="Films"
24. propose_forward i49 label="Films" pref=high
25. retrieve_likelihood i50 label="Celebrities" value=high
26. ...
27. Select: i49
28. apply_forward i56 ACTION (press "Films")

```

The model is now given a choice between two "low" rated labels. This time, no retrieval of a previous and highly rated operator occurs so one of the "low" operators is selected. (The 5% of trials on which participants chose to "give up" the search at points like this are not modeled.)

```

29. retrieve_likelihood i62 label="Careers" value=low
30. recognise_no i63 label="Education"
31. retrieve_likelihood i64 label="Education" value=low
32. propose_forward i65 label="Education" pref=low
33. recognise_no i66 label="Careers"
34. propose_forward i67 label="Careers" pref=low
35. ...
36. Select: i65
37. apply_forward i72 ACTION (press "Education")

```

In addition, to the above, the model was run on the range of label rating combinations used in the experiment and produced behavior consistent with the findings in each circumstance. We have not reported aggregated statistics of the models performance here, as the participant responses to which such an analysis would be compared were probably dependent on finer grain label ratings than were provided to the model. What is important for our current purposes is that the model captures the qualitative distinctions observed in the experiment.

Discussion

We have presented an integrated model of interactive search that is based on an instance-based account of human memory. The model captures findings from an experiment reported in the current paper and is consistent with previous findings (Howes and Payne, 2001). Specifically, while operator proposal is primarily display-based, operators are also proposed on the basis of memory for previous untried same-trial operators. We have claimed that this instance-based approach provides the fine discrimination for the source of memories that is required in order to model the data.

While we have empirically demonstrated that people moderate their willingness to select backup operators on the basis of memory for previous unselected alternatives, a threshold account may still be relevant to performance. For example, a threshold may be required to determine 'give up' decisions, and also to determine, at the first choice point, whether to select an item or scan for another. How this threshold is determined is an issue that requires further research.

There are many aspects of the interactive search data that we have not attempted to capture. Miller and Remington (2001), for example, describe a thorough analysis of how their model captures aspects of the depth/breadth trade-off in human performance with menu systems. It is possible that our model is consistent with Miller and Remington's threshold model in this respect but the analysis remains to be done.

The model that we have described can be contrasted to a method of search control known as operator subgoalings (Laird, Newell and Rosenbloom, 1987). With operator subgoalings, the best operator that has been proposed is selected even though it cannot be implemented directly in the current state. The operator is posted on the goal stack and the preconditions for operator application are posted as the current goal. In contrast, the search strategy that we have described here is relatively lean in the demands that it places on memory. When a decision was made that there was an attractive, previously experienced operator, this operator was not posted as the goal, rather the problem solver chose the single operator required to achieve the required preconditions. Once these have been met, the choices on the new menu are considered afresh and a choice made. In general, it is possible, that the greater power of the operator subgoalings mechanism is required to model human interactive search. It is often the case, for example, that establishing the preconditions for an operator requires more than one step. In this circumstance operator selection needs to be guided by a consistent focus on the desired preconditions. We see no reason why the instance-

based framework that we have described should not be capable of supporting this more sophisticated strategy.

Lastly, it is worth considering the fact that we have not chosen to include mechanisms of decay and interference in the model reported here. The reason for this is that these mechanisms were not required to capture the findings of the experiment. However control strategies often do not degrade gracefully as memory becomes unreliable. Implausible perseveration is, for example, a frequent consequence of the loss of critical information from the memory of a model. It is likely therefore that this issue will need to be revisited.

Abstract

The ability of members on a team to reason about each others' capabilities and workload is important for effective teamwork. This is required for proper task allocation and load balancing, as well as many other team processes such as adaptiveness, proactive assistance, and backing-up behavior. The present work proposes to incorporate capability reasoning into intelligent agents to produce better teamwork simulations, to work better with humans as virtual team members, and to facilitate team training. However, classical models of capabilities in computational systems and intelligent agents are inadequate for representing the more complex aspects of human performance, such as the ability to perform multiple tasks in parallel, interference among these tasks, effects of limits on attention and other cognitive resources, and the ability of humans to dynamically adjust their level of effort on tasks. In this paper, we present a formal mathematical model of capabilities that accounts for these effects. The model posits finite pools of internal resources, for which tasks compete; quality of performance depends on the amount of resources allocated. Capabilities are defined according to whether a feasible schedule can be found that allows a set of tasks to be completed within given constraints (e.g. deadlines) while not exceeding the capacity of any internal resource. An extension of the model is then proposed to incorporate multiple resources.

Introduction

Many studies have suggested that the ability to distribute tasks appropriately and to adaptively balance the workload within teams is essential for producing effective teamwork (Kleinman et al., 1992; Kozlowski, 1997). In order to do this, team members must be able to reason about their own and each others' capabilities. For example, they must be able to know when to accept or reject new tasks, based on how they might interfere with current on-going tasks, to delegate sub-tasks to the (best) team members who are not overloaded, and to offer assistance to those who are. Even in intra-team communication and coordination, assessment of capabilities and workload have an impact; in one study, it was found that communications among team members in the best-performing teams actually decreased in high-tempo situations (Serfaty et al., 1997), presumably

due to a recognition that excessive communication activities place a demand for attention on both the sender and receiver that competes with processing of intense taskwork. Therefore reasoning about capabilities, including knowledge of task demands, skill levels of individual team members, and momentary workload across the team in a given situation, must be considered an essential component of team cognition.

Recently there has been a rise of interest in incorporating intelligent agents into automated team-training systems (Rickel and Johnson, 1997). These agents could be used in a variety of ways, from automated assistants (decision aids), to virtual role players, to coaches. In order for agents to monitor, understand, critique, or participate in teamwork with human trainees, the agents must also be endowed with the ability to reason about capabilities and workload of individuals on the team. Agents in the simulation must be able to assess the workload of humans with whom they interact in order to make decisions about when and how to interact in a way that is not disruptive or unnatural. (This is an additional constraint that purely agent-based systems do not have to be concerned with.) However, most existing formal models of capability reasoning in agents do not adequately address the kind of reasoning that is required in these agent-based team-training systems. Typically, these prior models treat capabilities as a simple association between actors (agents or humans) and "executable" actions, though the actors must also be aware that they can do these things, i.e. have sufficient "know-how" (Moore, 1985; Singh, 1991; van der Hoek et al., 1994).

These computational models allow agent-based systems to be designed where the agents can reason about each others' capabilities, and even perform task distribution and load balancing. However, these models generally assume task completion is binary (success or failure) and do not take into account graded senses of capability, which are more meaningful to human performance. Humans can often achieve better results by working "harder" (applying more effort or attention), they can dynamically reduce their effort on one task to accommodate per-

forming other tasks in parallel, and they are often limited by pragmatic upper-bounds on performance (e.g. due to finite skills or attention). What is needed is a formal system that will enable an agent to understand when a human is too busy doing certain activities (e.g. flying an aircraft in combat or engaging an enemy) to do other things (e.g. monitor for new visual contacts, listen to background radio traffic). The agent needs to be able to compute the relative impact of new tasks on the accuracy of performing existing tasks, and the potential for delay in completion of individual tasks by their deadlines. This is different from just asking whether an operator is capable of doing the additional tasks "in principle."

Humans are capable of performing multiple tasks in parallel, and there is a great deal of literature on analyzing time-sharing performance (Wickens and Holland, 2000). Yet humans ultimately have limits on their processing capacity, exemplified by the notion of finite limits on attention, which has been rigorously documented. Furthermore, there is clear evidence that some task combinations are time-shared more efficiently than others, such as the difference between drawing a sketch while listening to the radio versus reading while listening to the radio. Some models, such as the multiple-resource model (e.g., Wickens, 1984) have postulated distinct and separate cognitive resources for different types of cognitive processing to explain the wide range of observed task interactions. Another important issue that makes human capabilities difficult to reason about is that performance is not a binary quantity, but rather a graded value (e.g. accuracy, reaction time), and humans can intentionally adjust task performance in a number of controllable ways, such as increasing quality by focusing attention and applying more cognitive "effort," or by reducing effort by spreading the task processing out over a longer interval of time (Hendy et al., 1997), such as multiplying multi-digit numbers together in one's head more slowly for greater accuracy. Therefore, whether or not a human member of a team is "capable" of doing something depends on a great many things, including what other tasks he or she is doing (their current workload), the degree to which the new task might interfere with them, the individual's skill level(s), attention management skill (Gopher, 1993), and the adaptability of the task performance with respect to the tightness of the constraints on completion (e.g. deadlines, quality criteria). This is a more situation-based or context-dependent perspective on capability.

Reasoning about capabilities at this quantitative level is important for modeling and understanding teamwork. To date, very little research has addressed the relationship between individual cognition and quality of teamwork, though the connection is discussed in (Huey and Wickens, 1993). An understanding of individuals' capabilities and workload

are clearly important to the efficient operation of a team, such as for distributing tasks to the most appropriate/skillful members, balancing the load (to maintain flexibility), and proactively assisting or backing each other up. With regard to training, we hypothesize that each team member him/herself must develop enough reserve capacity on top of their individual taskwork to devote some attention to participating in the teamwork, such as tracking status or progress of team goals, sharing information relevant to others, or building distributed situation awareness.

In this paper, we present a formal, mathematical model for reasoning about capabilities, especially for agents to reason about and interact with their human teammates. The approach synthesizes ideas from a number of previous descriptions of workload, attention, and performance into a computational model that can be concretely implemented as a decision-making procedure in a multi-agent system. After establishing some terms and assumptions, a definition of capability will be presented in terms of whether a human could adapt his or her performance (i.e. to find a schedule and select effort levels) that would accommodate a given set of tasks with a set of specified constraints. We conclude by discussing the implications of this computational model of capabilities for modeling and understanding team performance, and for designing new approaches to team training.

A Formal Model

In this section, we present a quantitative model for reasoning about capabilities. For simplicity, we start with description of a single-resource model as a basis. Later we extend it to show how it can accommodate the assumption of multiple cognitive resources.

Single-Resource Foundation

Preliminarily, assume there is a single common cognitive resource for which tasks compete. Perhaps it might be labelled generically as "attentional resources." At any given time, a person might be using some amount of this resource, $u(t)$, but the resource is bounded, $\forall t \ 0 \leq u(t) \leq u_{max}$. Since the scale is arbitrary, we normalize resource utilization so that $u_{max} = 1.0$, putting it on a uniform scale of 0 to 1.

We assume this common resource can be allocated to, or divided among, several concurrent tasks. The amount of resource being applied to a given task i at a given moment t is referred to as "effort," and is denoted $e_i(t)$. We view the sum of resources being applied to all tasks at a given moment as a reflection or internal measure of workload. Let the set of tasks be called $\tau_1 \dots \tau_i$. The "workload" is defined as:

$$w(t) \equiv \sum_i e_i(t)$$

and it is constrained not to exceed the limit, $0 \leq w(t) \leq u_{max}$.

Figure 1: Resource utilization over time (with limit).

Whereas this notion of effort is defined on a moment-by-moment basis, the total effort expended on a task, or total resources applied E_i , is the sum of the effort allocated to that task over the duration of its performance (illustrated in Figure 1). In other words, it is the sum, or integral, of the moment-by-moment resources utilized in performing that task:

$$E_i \equiv \int_{t=start(i)}^{t=end(i)} e_i(t) dt$$

While the amount of resources applied to a task is not necessarily constant, we assume there is an average effort value \bar{e}_i , and our model is based on this approximation.

The amount of resources required for an individual to perform a given task depends on a number of internal and external determinants. Externally, the difficulty of the task, as well as constraints on accuracy or speed (i.e. deadlines), can influence the processing resources required (e.g. it is harder to do a task better or faster, and some tasks have parameters related to difficulty, such as number of items to remember, and so on). Internally, a specific individual's response to task demand can be affected by their innate ability and executive management skill, prior training, degree of automation, etc. We quantify the relationship between amount of resources applied to a task and quality of performance using a function for quality-effort tradeoff: $q_i = f(E_i)$ (also known as a Performance Resource Function (Norman and Bobrow, 1976); see Figure 2).¹ Quality can represent any number of performance measures specific to the task, such as accuracy, inverse of reaction time, etc. We do not place many restrictions on the form of this function, but typically, we assume it is monotonic: increasing effort on most tasks increases quality (Wickens, 1984). (Often, they reach a plateau where greater effort does not improve quality, in which case they are said to be "data-limited.")

¹Quality of performance might also depend on some measure of task difficulty, which can be treated either by adding an argument for whatever variable parameterizes the degree of difficulty, or by simply viewing them as separate tasks.

Figure 2: Illustration of a Performance Resource Function.

Humans can apply the same amount of total effort to a task in a range of different ways. In particular, they might choose to work as hard as possible on the task, completing it in a short amount of time, or they might decide to spread the processing out over time, reducing the moment-by-moment effort, for example to have some reserve capacity left over to apply to other tasks in parallel. Given that we model effort applied as the integral of resource utilization over time, and we assume there is an average level of effort dedicated to a task, the relationship among momentary effort, total effort applied, and duration may be expressed as a simple formula:

$$E_i = \bar{e}_i \cdot d_i$$

where $d_i = end(i) - start(i)$ is the duration of the task. Therefore, the effort-duration tradeoff may be represented as a (presumably) hyperbolic function, and different levels of total effort appear as iso-curves (see Figure 3). Each point on a given curve bounds a box of constant area, representing the common degree of total effort. Harder versions of the same task correspond to curves farther out (dashed line in Figure 3), and improvements in ability, e.g. due to training, appear as curves closer to the origin.

We assume there are range bounds on both duration and effort. Of course, a task can utilize no more than 100% of a resource, and this puts a bound on the minimum execution time (speed), as a result of the hyperbolic function. Similarly, we assume there is a minimum amount of resource required, and a corresponding limit on the slowest effective rate of performance. We represent these ranges as $(d_{i,min}, d_{i,max})$ and $(u_{i,min}, u_{i,max})$.

The performance-resource function is not only a function of task, but also of the individual. We model the difference among individuals by assuming the form of the equation is the same, and applying a multiplier that represents their degree of skill s of individual j (relative to the average of the population, for which we set $\bar{s} = 1$):

$$q_{j,i} = f(E_i) \cdot s_{j,i}$$

Figure 3: Effort iso-curves.

Hence the greater the skill, the greater the quality of performance for a fixed amount of effort (can be visualized as higher curves in Figure 2). This allows us to model the differences between novices and experts in a simple way.

Capability Assessment as Scheduling

Given this quantitative model of task performance, we can now offer an initial formal definition of "capability." Recall that we are interested not just in whether an individual is capable of doing something "in principle," but also whether it can be carried out effectively in the time allotted and to the level of quality or accuracy required, all within the context of other on-going activities. We view this as a kind of "scheduling" problem, where capability is determined by whether or not the individual can find an arrangement of processing so that all the tasks can be completed without violating any internal capacity limitations.

Definition 1: A *schedule* for a set of tasks $\tau_1 \dots \tau_n$ being processed or executed by an individual is a set of parameter vectors $\{(start(i), end(i), \bar{e}_i)\}$ defining the start and end times of each task, along with planned average resource utilization to be applied to each.

Definition 2: An individual j who is currently performing a set of tasks $\tau_1 \dots \tau_n$, with quality constraints $q_1 \dots q_n$ and deadlines $dl_1 \dots dl_n$ is said to be *capable* of performing a new task τ_{n+1} (with constraints q_{n+1} and d_{n+1}), if there exists a schedule S over $\tau_1 \dots \tau_{n+1}$ defining the start and end times along with average resource utilization of each task $\langle start(i), end(i), \bar{e}_i \rangle$, such that all constraints remain satisfied. Specifically:

1. $q_i \leq f_j(E_i) = f(\bar{e}_i \cdot (end(i) - start(i)))$,
2. $end(i) < dl_i$, and

Figure 4: Example of task schedule.

3. $\forall t \ w(t) = \sum_i \bar{e}_i \leq u_{max}$, where the sum runs over all tasks i s.t. $start(i) \leq t \leq end(i)$.

We note that, among the existing tasks, some may currently be being processed, while others may be scheduled to start after some delay (i.e. pending tasks). If processing of certain currently executing tasks is considered uninterruptible, then we require $start(i) = t_{now}$ for those tasks in the revised schedule to maintain continuity (though the effort level may be modified). Figure 4 shows an example of a task schedule, with selected effort levels and durations, and some representative constraints.

The point of this definition of capabilities is that determination of capability in context must be done flexibly, since there are a wide variety of ways in which performance of tasks can be rearranged to accommodate multiple on-going activities. One primary mechanism is delaying processing of tasks that are not as time-critical. This naturally leads to a scheduling metaphor (Tulga and Sheridan, 1980). Various scheduling algorithms can be drawn from other fields, such as real-time systems. While exact solutions to these problems are often provably intractable, reasonably efficient approximation algorithms often exist (e.g. greedy, earliest deadline first, most-difficult task first, etc.). A major open question is: which approximations seem to correspond to the kinds of heuristics humans use in deciding how to carry out multiple tasks in complex environments?

One unique characteristic of this application of scheduling is that, in addition to manipulating start and end times, another dimension taken into account is the level of effort. In other words, individuals have the option of reducing or increasing their resources allocated to a given task, which can result in a corresponding increase or decrease in duration required to produce equivalent performance. Hence, one may decide to defer processing of a new task until the existing ones are complete, or, if there is insufficient time, may decide to begin processing the new task right away by shifting some of their emphasis or at-

tention away from the current tasks, as long as it will not threaten their successful completion.

Using our scheduling-based definition of task performance under resource constraints (both internal and external), we can implement a concrete, computational method for agents to estimate workload of humans and use it to simulate decision-making about when they are likely to accept or reject new tasks in a dynamic environment. Specifically, the model would predict task acceptance if and only if a feasible schedule can be found (at least by a reasonably plausible heuristic method) that would accommodate the new task along with all existing ones, where they would all be completed in time to meet their respective deadlines, and the effort requirements (workload) would not exceed the limits (maximum capacity) of the internal cognitive resource.

A pragmatic issue in developing such a computational method is that the performance characteristics for each individual would need to be derived. We believe that these parameters can be inferred from empirical observations under various controlled conditions by using data-mining techniques, but a detailed description of the methodology is outside the scope of this paper.

Extension to Multiple Resources

The problem with the model as we have presented up to this point is that it is based on a single-resource assumption; thus it cannot account for variable degrees of interaction among tasks of different types. To extend our model to incorporate multiple resources, we start by assuming that there is a fixed set of resource pools, $r_1 \dots r_n$. For example, these might represent the eight components in Wickens' (2000) model, with resources for: auditory input processing, visual input processing, perceptual/central processing, response processing, spatial processing, verbal processing, manual response processing, and speech response processing. Each of these is postulated to be used to different degrees (possibly zero) by any given task.

Thus, instead of a univariate curve for the performance-resource function, we have in principle a function of n dimensions, representing allocation of each resource independently (Tsang and Velasquez, 1996). However, to keep the model manageable (and for parsimony), we instead use a "profile" for each task to represent, under single-task, full-attention conditions, the relative amounts of each resource required: $\langle u(r_1), \dots, u(r_n) \rangle$ (as illustrated in Figure 5). Then each resource level is modified proportionally based on what fraction of 100% attention, $att(\tau)$, is allocated to a given task τ in a specific situation, effectively parameterizing the resource demands. Hence the task demand, distributed over the various resource components, becomes:

$$\langle att(\tau) \cdot u(r_1, \tau), \dots, att(\tau) \cdot u(r_n, \tau) \rangle$$

Figure 5: Resource-demand profile for a hypothetical task. The open bars represent the relative amount of demand by a task on each type of internal (cognitive) resource when it is being given full attention. The solid bars show resource allocation levels scaled down proportionally for a case where an individual is only able to focus half of the requisite attention on this particular task.

This approach allows us to treat task performance as intrinsically multi-dimensional. Now the rest of the model (including scheduling) can be applied as before, with the condition that, regardless of how the tasks combine or overlap, no individual resource may exceed its capacity at any point in time:

$$\forall t \ w_k(t) = \sum_i att(\tau_i, t) \cdot u(r_k, \tau_i) \leq u_{max}(r_k)$$

for all resource pools k , where i is summed over all tasks being executed at time t . The task difficulty and quality (i.e. accuracy) requirements set the level of effort required for the individual, the individual chooses a suitable duration and corresponding level of average emphasis to apply, and then this is used to compute utilization of each resource based on a scaled version of the single-task utilization profile. To determine whether an individual is capable of accepting a new task in the context of existing ones, a schedule must be sought that allows all tasks to complete within the time and quality constraints, while violating no limits on internal resources.

The primary benefit of this multi-dimensional model is that it can be used to simulate different degrees of interference among tasks depending on their type. For example, even though tasks A, B, and C are considered equally demanding, it might be more efficient to process A and C in parallel than A and B. This effect could be captured by saying that the profiles for A and B both share high demand for the same underlying resource, while the components utilized by A and C are relatively distinct. The phenomenon of differential interference based on task type has been called "structural similarity" in the literature (Wickens and Holland, 2000). Our work

is intended to form a preliminary basis for theoretical and empirical modeling of this effect.

Discussion

Capabilities and workload are one part of the "shared mental model" that must be computed, along with others' beliefs, goals, situations, etc., to generate believable simulations of teamwork. This model could be applied to enhancing the simulation and generation of teamwork by influencing role selection, delegation, negotiation, and pro-active behavior. For example, responsibilities could be re-defined to take into account the degree to which one is capable of doing something, delegation policies and task allocation strategies could be modified to reflect an awareness of individuals' workload (i.e. to select a member for whom it would least interfere), and agents could adjust their initiative in offering to help team members with tasks based on an assessment of how over-loaded they are versus how much of a distraction it would be.

An important application of this computational model of capabilities could be for designing intelligent agents for use in team-training systems. Specifically, this model would allow agents to monitor, exercise, and evaluate individuals' ability on human teams to appropriately and effectively participate in the teamwork, as a function of their own skills, workload response, and attention management strategies. The goal would be the development of novel training interventions that could promote the balance of the cognitive demands of taskwork versus teamwork (i.e., spending time reasoning about each other).

Abstract

We present a novel self-organizing structure recognition (SOSR) network for classification and recognition of relational structures represented by graphs. The system consists of several subnets each comparing an input structure with a given model structure. The subnets are indirectly coupled via a winner-take-all (WTA) classifier. During classification the SOSR system deactivates subnets which indicate large dissimilarities between the input structure and the corresponding models. First experiments show that this mechanism significantly reduces the computational effort in comparison to traditional classification systems using a comparative maximum selector as a classifier.

Introduction

We describe a hierarchical neural net for the recognition and classification of relational structures by matching with class prototypes which was primarily developed from a theoretical point of view and for practical applications in Artificial Intelligence. Classification by means of prototypes is well known in the psychological literature (e.g. Rosch, 1975; Rosch and Lloyd, 1978) but usually is modeled using feature vectors as description of objects and prototypes, respectively. In the context of modeling semantic memory and discussion of the binding problem in Cognitive Neuroscience relational descriptions and representations of structured objects play nowadays a major role (e.g. Hinton, 1994; Taylor, 1993; Taylor, 1996; Singer, 2000). Seen from the point of view of modeling the dynamics of neural structures in connection with psychologically observed behavior we are not primarily interested in the neural (population or assembly) code of representing relations (e.g. Singer, 2000) but in studying the processing strategies using symbolic descriptions of objects and prototypes by graphs and a hierarchical organized *winner-takes-all* (WTA) net. This net will classify objects by competitive matching with a set of predefined prototypes in a *self-organizing manner*, i.e. without a *homunculus* acting as a supervisor. The investigation of the WTA-processing strategies might also shed light on principles of functioning of the Short-Term-Memory (e.g. Grossberg, 1987a; Grossberg, 1987b), on the role of attention

(Lee et al., 1999), and on a trade-off between accuracy vs. speed of recognition depending on the strength of inhibition as shown in our first experimental results given below.

In Artificial Intelligence and Image Recognition graphs are a well suited representation of relational structures like molecular structures, data structures, or semantic networks. In any case, a relational structure consists of elementary objects and binary relations between these objects. In a graph of a relational structure the elementary objects are represented by vertices and their relations by directed or undirected edges. For example, in chemistry, graphs model molecular structures where the vertices represent atoms and the edges represent bonds. In Computer Vision vertices of a graph are objects within a scene and edges are structural relationships between those objects.

A fundamental problem in many application domains of processing relational structures is the identification and recognition of common structural parts between two relational structures. For example in classification, recognition or clustering tasks, information about structural overlaps between two structures is required in order to determine a similarity or distance of these structures. Here we call the computation of a similarity or distance between two relational structures *graph matching*.

In general graph matching problems are well-known NP-complete problems (Garey & Johnson, 1979). Due to the high computational complexity much effort has been directed toward devising efficient heuristics to find optimal or approximate solutions for graph matching problems. Among other heuristics artificial neural networks have been proposed as a promising model of computation for solving graph matching problems (Schädler & Wysotzki, 1999).

The high computational complexity is even more inconvenient if the solution of a problem requires several graph matching procedures. In distance-based classification using neural networks an input graph G is matched against a given set of N model graphs M_1, \dots, M_N representing prototypes of category C_1, \dots, C_N , respectively. The matching is performed by recurrent neural networks S_1, \dots, S_N . In

the following we will call these networks S_k subnets.

One fundamental approach in distance-based classification of structures is the classification by means of a *discriminant function* and a *comparative maximum selector* (CMS) classifier. A classification task is solved by a CMS approach in the following chronological order (Schädler & Wysotzki, 1999): (1) A feature extractor computes the discriminants ϱ_k of input G and each model M_k . The discriminant ϱ_k is computed by the k -th subnet S_k and serves as a measure for the similarity between G and M_k . (2) The discriminants are passed to a CMS classifier. (3) The CMS classifier sequentially compares the calculated discriminants and assigns the input graph to the category for which the corresponding discriminant is largest. Thus a CMS classifier processes its incoming data like a supervising *homunculus*.

In the traditional CMS classifier approach each match between G and M_k has equal priority in the sense, that each subnet S_k evolves until it has computed a discriminant ϱ_k for G and M_k . Thus a CMS classifier completes the evolution of all N subnets although the internal states of some subnets may indicate high dissimilarity of the graphs to be compared at an *early stage* during the matching process.

In order to improve the computational performance of a classifier for relational structures and to investigate the effects of self-organization in hierarchical networks we present a *self-organizing structure recognition* (SOSR) network. To accomplish a better computational performance than the CMS classifier the SOSR model identifies dissimilar pairs G and M_k at an early stage of the matching process and aborts the computation of the corresponding subnets S_k . Thus the SOSR network focuses on promising subnets and neglects subnets indicating high dissimilarity between the input and the corresponding model. This mechanism is realized by replacing the CMS by an inhibitory WTA network for the maximum selection and intertwining the tasks of step (1)-(3). Further improvements to reduce the computational effort can be made by parallel processing which is not possible with a sequential CMS classifier.

Note, that the SOSR model has much in common with the *competitive relational mind model* proposed by Taylor (1996). Furthermore, Grossberg (1987a) uses in a similar way a network for competitive learning with a reset mechanism which deactivates subnets announcing high dissimilarity to allow them to rebuild the model, i.e. the expectation.

The rest of this paper is organized as follows: We conclude this introductory section with some basic notations and definitions. In the next Section we formulate the graph matching problem in terms of the maximum clique problem. Subsequently we describe the SOSR network architecture. In an empirical study we investigate the behavior of the SOSR system. Finally, the last section summarizes this

contribution.

Notations and Definitions: A *graph* is a pair $G = (V, E)$ consisting of a finite set $V \neq \emptyset$ of *nodes* and a binary relation $E \subseteq V^2 := \{(i, j) \mid i, j \in V, i \neq j\}$. The elements $(i, j) \in E$ are called *edges*. A *subgraph* $H = (V_H, E_H)$ of G is a graph with $V_H \subseteq V$ and $E_H \subseteq V_H^2 \cap E$. An *induced subgraph* H of G is a subgraph with $E_H = V_H^2 \cap E$. A graph G is called *complete*, if $E = V^2$. A complete subgraph $C \subseteq G$ is called *clique* of G . A *maximum clique* $C \subseteq G$ is a clique with maximum number of vertices. A *maximal clique* is a clique which is not contained in any larger clique. The *clique number* $\omega(G)$ of a graph G is the number of vertices of a maximum clique in G . The *size* n_V of a graph G is the number $|V|$ of its vertices.

Graph Matching and Maximal Cliques

The graph matching problem is the problem to find the best partial mapping between two graphs where the quality of the mapping is estimated in terms of a problem dependent objective function. Our SOSR approach can also be applied to inexact graph matching problems of colored graphs, where vertex colors represent elementary objects and edges colors represent the type of relation between these objects. But for convenience we only consider the common maximum induced subgraph problem which comprises the graph isomorphism and subgraph isomorphism problem as special cases.

A common approach to solve these classes of graph matching problems is based on maximum clique detection in an *association graph* (Ballard & Brown, 1982)). The association graph is formed by creating vertices i from each pair of vertices $(i_1, i_2) \in V_1 \times V_2$ and inserting edges between vertices $i = (i_1, i_2)$ and $j = (j_1, j_2)$ if (i_1, j_1) and (i_2, j_2) are edges in G_1 and G_2 , respectively.

By definition of an association graph the cliques of $A = A(G_1, G_2)$ are in 1-1 correspondence to common isomorphic induced subgraphs of G_1 and G_2 and the maximum cliques uniquely correspond to the common maximum induced subgraphs of G_1 and G_2 . This maps the graph matching problem to the optimization problem of finding a maximum clique C in A where the discriminant $\varrho(A)$ is a function on the number of vertices of C .

The SOSR Model

In the following let $A_k = (V_k, E_k)$ be the association graph of input G and model M_k ($1 \leq k \leq N$), where M_k represents category C_k . With ϱ_k we denote the discriminant of A_k .

The SOSR model consists of two interconnected layers, a feature extractor layer and a classifier layer (see Figure 1). The feature layer contains N subnets S_k each comparing input G with model M_k . The

classifier layer is a competitive WTA network for the maximum selection consisting of N inhibitory connected units where unit c_k represents category C_k . Each subnet S_k of the feature extractor is connected to unit c_k of the WTA classifier via an inter-unit i_k .

Figure 1: Architecture of a SOSR network.

During classification the subnets S_k evolve synchronously and continuously pass their current internal states to the inter-units i_k . The inter-units compute interim values $\rho_k(t)$ of the discriminants ρ_k and transfer them to the WTA classifier. The WTA classifier evaluates the evidence presented for a decision at an early stage. If the activation $z_k(t)$ of unit c_k in the classifier layer falls below zero, the WTA network disconnects unit c_k from inter-unit i_k , such that subnet S_k is excluded from the competition.

Figure 1 depicts a functional diagram of the SOSR model for the $N = 3$ category problem. The shading of units c_k in the classifier layer indicates their output level where darker shading means a higher output. Thus unit c_1 is dominating while unit c_2 has the lowest activation. Inter-units i_k are depicted as switches. A subnet S_k participates in the competition if the connection between S_k and c_k is switched on. Otherwise, S_k is considered to be irrelevant for the decision making process and inter-unit i_k switches off the connection to exclude S_k from the competition. In figure 1 inter-unit i_2 disconnects subnet S_2 from the classifier layer.

In mathematical terms the following equations describe the behavior of the SOSR model:

$$\dot{x}_i^k(t) = -dx_i^k(t) + \sum_j w_{ij} f(x_j^k(t)) \quad (1)$$

$$y_k(t) = \left[\left[\rho(x_k(t)) \right]_0^1 + \varepsilon - s_\varepsilon(-z_k(t)) \right]_0^1 \quad (2)$$

$$\dot{z}_k(t) = -d' z_k(t) - w \sum_{j \neq k} [z_j(t)]_0 + y_k(t) \quad (3)$$

where $[x]_\theta^\vartheta := \max\{\theta, \min\{x, \vartheta\}\}$ is the limiter function with lower and upper bound $\theta < \vartheta$, $[x]_\theta :=$

$\max\{\theta, x\}$ is the linear threshold function with lower bound θ , and s_ε is a trigger function of the form

$$s_\varepsilon(x) = \begin{cases} 1 + \varepsilon & : x \geq 0 \\ 0 & : x < 0 \end{cases}$$

Equation (1) describes the dynamics of an additive recurrent subnet S_k in the feature extractor, equation (2) describes the behavior of inter-unit i_k connecting subnet S_k with unit c_k of the WTA net, and equation (3) specifies the WTA dynamics. The system terminates if only a single unit c_{k_*} in the WTA classifier is left with an activation $z_{k_*}(t) > 0$ while all other units c_k are inhibited, i.e. $z_k(t) \leq 0$. Under the assumption of converging subnets termination follows from (Jain & Wysotzki, 2001a; Wersing & Beyn & Ritter, 2001).

Equation (1): A Maximal Clique Solver

Let index k refer to subnet S_k solving the maximum clique problem for graph A_k .

Many different neural network approaches and techniques have been proposed to solve the maximum clique problem (Bomze et al., 1999). As a representative model we consider a general additive recurrent network (1) where $x_i^k(t)$ denotes the activity of unit i of subnet k at time t and the constant $d \in [0, 1]$ describes the self-inhibition. The strength of the connection between unit i and unit j is determined by the synaptic weight $w_{ij} = w_{ji}$. The output of each unit is computed by a non-decreasing bounded function f .

In order to solve the maximum clique problem of the k -th association graph $A_k = (V_k, E_k)$ the network consists of $|V_k| = n_k$ units which are connected with weight $w_{ij}^k = w_{ji}^k > 0$ if $(i, j) \in E_k$ is an edge in A_k and with weight $w_{ij}^k = -w_{ji}^k < 0$ if $(i, j) \notin E_k$. Self weights w_{ii}^k are set to zero.

Given appropriate parameter settings the maximal clique solver operates as follows (Schädler & Wysotzki, 1998; Schädler & Wysotzki, 1999): An initial activation is imposed on the network. Finding a maximum clique then proceeds in accordance with equation (1) until the system reaches a stable state. The stable states correspond to the maximal cliques of A_k . In the ideal case a maximum clique is found. The clique size can be read out by counting the number of units with activation $x_i^k(t) \geq 1$.

For our experiments we used the time-discrete approximation of (1) given by

$$x_i(t+1) = (1-d)x_i(t) + \sum_{j \neq i} w_{ij} f_T(x_j(t)) + \eta(t) \quad (4)$$

where $\eta(t)$ is a small random noise to dissolve ambiguities and f_T is a controllable limiter function of the form

$$f_T(x) = \begin{cases} 1 & : x \geq T \\ 0 & : x \leq 0 \\ x/T & : \text{otherwise} \end{cases}$$

with control parameter T which we call the *pseudo-temperature*. Starting with a high initial value for $T = T_0$ the pseudo-temperature T is decreased during the evolution of the network according to an annealing schedule until it reaches a sufficient low final value $T = T_f$. Applying an annealing scheme avoids that the system gets stuck in spurious minima. The annealing schedule is of the following form:

1. Initialize $T \leftarrow T_0$.
2. Let the network iterate τ steps according to the dynamical rule given in (4).
3. Decrease the pseudo-temperature by $T \leftarrow a \cdot T$ where $0 < a < 1$ is an annealing constant.
4. If $T > T_f$ continue with step 2. Otherwise terminate the algorithm.

The general parameter settings of the subnets S_k follows a theoretical analysis given in Jain & Wysotzki (2002). For the weights we set

$$\begin{aligned} w_E^k &= \frac{2}{\deg_I^k \cdot (n_k - \deg_E^k)} \\ w_I^k &= \deg_E^k \cdot w_E^k \end{aligned}$$

where n_k is the number of units of subnet S_k and \deg_E^k (\deg_I^k) is the maximum number of excitatory (inhibitory) connections of an unit in S_k .

Equation (2): Inter-Units:

An inter-unit i_k connects subnet $S_k = (V_k, E_k)$ with unit c_k in the WTA classifier and controls the external input $y_k(t)$ of c_k .

Let $\mathbf{x}_k(t)$ be the current state vector of subnet S_k . Inter-unit i_k receives $\mathbf{x}_k(t)$ as its input and computes an interim value $\varrho_k(t) = \varrho(\mathbf{x}_k(t))$ of the discriminant ϱ_k . The computation of interim values $\varrho_k(t)$ is constrained to

$$\varrho_k(t) \leq \varrho_k \quad (5)$$

where equality holds if and only if S_k is in a stable state corresponding to a maximum clique. The discrimination value ϱ_k measures the resemblance between input G and model M_k . Thus the interim values $\varrho_k(t)$ reflect a preliminary estimate of the discriminant ϱ_k where the degree of resemblance of G and M_k gradually emerges with the time spent on the matching problem. This is indicated by (5). At beginning an interim value $\varrho_k(t)$ is at a low level and with increasing time $\varrho_k(t)$ approaches ϱ_k . During evolution of S_k it is not required that $\varrho_k(t)$ is monotonously increasing with the time. We call local maxima and minima of $\varrho_k(t)$ *deceptions*. Deceptions may lead to misclassifications. A local minimum of $\varrho_k(t)$ may result in an exclusion of S_k from the competition. In this case the resemblance of G and M_k is underestimated during the comparison

of the structures G and M_k . Similarly, a local maximum of $\varrho_k(t)$ may result in a premature decision which assigns G to category C_k . Here the match of input G and model M_k is overestimated during computation. Another source of misclassifications arise from insufficient synchronization among the evolving neural maximal clique solvers S_k . Here, too fast (too slow) convergence of $\varrho_k(t)$ to a low (high) discriminant ϱ_k can lead to an erroneous decision. Thus it is an important objective to design the computation of $\varrho_k(t)$, such that deceptions are avoided and the matching procedures of the subnets S_k are synchronized.

Depending on its current state $y_k(t)$ an inter-unit i_k transfers the interim value $\varrho_k(t)$ to unit c_k of the WTA classifier. An inter-unit i_k is in state ON if $y_k(t) > 0$ and in state OFF if $y_k(t) \leq 0$. Only inter-units in state ON pass interim values to the WTA classifier. Initially, the state of each inter-unit is ON where $\varepsilon > 0$ is a small constant to avoid a deactivation of i_k at the beginning. According to (3) let $z_k(t)$ be the activation of unit c_k in the WTA classifier. Unit c_k switches OFF inter-unit i_k if $z_k(t) \leq 0$ and does not effect i_k otherwise. This mechanism is realized by the trigger function s_ε . If $z_k(t) \leq 0$ then $-z_k(t) \geq 0$ and thus the value $s_\varepsilon(-z_k(t)) = 1 + \varepsilon$ is subtracted from $\phi_k(t) + \varepsilon \leq 1 + \varepsilon$. This sets the activation level $y_k(t)$ of inter-unit i_k equal to 0. Similarly, if $z_k(t) > 0$ the trigger function s_ε has no influence on the activation $y_k(t)$ of inter-unit i_k . Once in state OFF an inter-unit can not be reactivated. In practical applications the corresponding subnets S_k can be switched off.

Next we give an example how to compute the interim values $\varrho_k(t)$ on the basis of a family of discriminant functions

$$\varrho_k = \frac{\alpha|V_{C_k}| + \beta|E_{C_k}|}{\mu_k}$$

where $\alpha, \beta \geq 0$ are problem specific constants which weight the vertex and edge matches, $C_k = (V_{C_k}, E_{C_k})$ is a maximum clique of A_k , and $\mu_k > 0$ is a normalization constant to ensure an upper bound of 1. Note, that $1 - \varrho_k$ defines a family of distance metrics (Schädler & Wysotzki, 1999). We define $\varrho_k(t)$ to be a function on the number of θ -active units:

1. Let $V_k^\theta \subseteq V_k$ be the set of θ -active units with activation $x_i^k(t) \geq \theta$ where $0 \leq \theta \leq 1$ is a threshold. Compute the current θ -intensity

$$\sigma_V^\theta(t) = \sum_{i \in V_k^\theta} [x_i^k(t)]_\theta^1 \quad (6)$$

2. Let E_k^θ be the set of all excitatory connections (i, j) between θ -active units $i, j \in V_k^\theta$. Compute

the current θ -connective-intensity

$$\sigma_E^\theta(t) = \sum_{(i,j) \in E_k^\theta} [x_i^k(t)]_\theta^1 + [x_j^k(t)]_\theta^1 \quad (7)$$

- Let I_k^θ be the set of all inhibitory connections (i, j) between θ -active units $i, j \in V_k^\theta$. Compute the current θ -incompatibility

$$\sigma_I^\theta(t) = \sum_{(i,j) \in I_k^\theta} \pi_{ij}^k(t) \quad (8)$$

where $\pi_{ij}^k(t) \geq 0$ is a penalty term for the presence of inhibitory connected active units.

- Compute the current interim value

$$\varrho_k(t) = \frac{\alpha \sigma_V^\theta(t) + \beta \sigma_E^\theta(t)}{\mu_k} - \sigma_I^\theta(t) \quad (9)$$

as a function of the current θ -intensity, the current θ -connective-intensity, and the current θ -incompatibility.

The appropriate choice of $\pi_{ij}^k(t)$ is crucial to synchronize the subnets and to avoid deceptions. Too high or too low values of $\pi_{ij}^k(t)$ result in a higher percentage of misclassifications.

Note, that in a stable state of S_k the interim values $\varrho_k(t)$ are identical to the discriminant ϱ_k defined by a corresponding maximal clique C_k .

Equation (3): A WTA Classifier:

The dynamical system given by equation (3) is an inhibitory WTA network for the maximum selection from a set of external input signals where unit k represents category C_k , $z_k(t)$ is the activation of unit c_k , $-w < 0$ represents the inhibitory strength of the synapses connecting any pair of units, $d' > 0$ is the self-inhibition, and $y_k(t)$ is the external input from inter-unit i_k .

Given an initial input vector the operation of these networks is a mode of contrast adjustment and pattern normalization where only the unit with the highest activation fires and all other units in the network are inhibited after some setting time (Jain & Wysozki, 2001a; Jain & Wysozki, 2001b).

In the context of the relational mind model of Taylor (1996) the WTA classifier may be seen as the analogue of the thalamic NRT-C complex acting as a central executive for global competition.

Experiments

In first experiments we focused on the performance of the proposed SOSR model and on the role of the inhibition $-w$.

To keep the experiments simple we considered the more general task of identifying a graph A_{k_0} with

n_v / t_{MS}	25 / 180.1		50 / 341.3	
w	κ	t_{SO}	κ	t_{SO}
0.2	1.00	18.8	0.95	33.0
0.1	1.00	19.2	0.95	44.0
0.01	1.00	75.2	0.99	97.5
0.001	0.99	167.3	0.94	251.1
0.0001	0.99	178.7	0.85	323.7

Table 1: Classification accuracies κ and number of iterations t_{SO} for size $n_V = 25$ and $n_V = 50$.

maximal clique number ω_{k_0} among a set of $N = 10$ graphs A_1, \dots, A_N of identical size $n_V := |V_1| = \dots = |V_N|$. For a single run of the algorithm with fixed size n_V the clique numbers $\omega_1, \dots, \omega_N$ of the N graphs were drawn from a Gaussian distribution restricted to the interval $[3, n_V - 1]$ with identically distributed random mean $3 \leq E[\omega] < n_V$ and variance $0 < \text{Var}[\omega] < n_V/2$. The chosen sizes are $n_V = \{25, 50, 100, 250\}$. To assess the effects of the inhibition $-w$ we varied the weight $w = \{20^{-1}, 10^{-1}, 10^{-2}, 10^{-3}, 10^{-4}\}$. We performed 100 runs of the SOSR algorithm for each chosen n_V and w .

Parameter Settings: We have chosen $T_0 = w_E \cdot \text{deg}_E^2 + w_I \cdot \text{deg}_I^2$, $T_f = 0.1$, $\alpha = 0.75$, and $\tau = 0.6 \cdot n_V$ as parameters for the annealing schedule of the subnets S_k . The self-inhibitions d and d' of the subnets S_k and the WTA classifier are set to 0.

To compute the discriminants we set $\alpha = 0$, $\beta = 1$, $\theta = 0$, $\varepsilon = 0.1$, and $\mu_k = \varepsilon^{-1} \cdot \omega_{k_0}^2$ for all k where ω_{k_0} is the maximal clique number of a sample $\omega_1, \dots, \omega_N$. The θ -incompatibility $\sigma_I^\theta(t)$ is defined by the heuristically chosen penalties $\pi_{ij}^k(t) = \frac{4}{n_V} ([x_i^k(t)]_\theta^1 + [x_j^k(t)]_\theta^1)$.

Results: Table 1 and 2 summarizes the results. The first row shows the size n_V and the average iterations t_{MS} of a subnet *without switching OFF*, averaged over all N subnets and all 500 runs for size n_V . The other entries show for each size n_V the rate of correct classifications κ and the average iterations t_{SO} of a subnet *with switching OFF*, averaged over all N subnets and all 100 runs for a given weight $-w$ and size n_V . For example a subnet S_k consisting of 150 units in a 10-category SOSR system with $w = 0.01$ averages 230.8 iterations until it terminates. In a CMS classifier system S_k averages 993.7 iterations. The classification accuracy of the SOSR system for this configuration is 0.92.

Discussion: If the inhibition $-w$ in the WTA classifier is on a low level an increase will tend to more accurate and faster generated responses. But when

n_v / t_{MS}	100 / 571.0		150 / 993.7	
w	κ	t_{SO}	κ	t_{SO}
0.2	0.89	45.5	0.83	140.0
0.1	0.94	49.9	0.84	130.3
0.01	0.94	126.4	0.92	230.8
0.001	0.87	361.9	0.92	604.3
0.0001	0.74	543.7	0.67	882.0

Table 2: Classification accuracies κ and number of iterations t_{SO} for size $n_v = 100$ and $n_v = 150$.

inhibition is at a high level, the increased competition may interfere with correct decisions by trapping into deceptions or by immobility in finding any response. Thus there will be an optimal level of inhibition for effective behavior. The optimal setting of w compromises the conflicting tasks of significantly improving the computational efforts and gaining high classification accuracy.

Conclusion

We introduced a new self-organizing structure recognition system. The architecture couples the subnets in the feature extractor to a WTA classifier such that the subnets are in an indirect competition during the matching process. The system consecutively switches off subnets if their interim values indicate a worse match than the remaining active subnets and shifts its attention to more promising subnets. In first experiments we showed that the switching-off mechanism of the SOSR system significantly reduces the computational effort without suffering in substantial losses of classification accuracy. The inhibition $-w$ of the WTA classifier controls the conflicting interests of high classification accuracy and fast decision making.

Integrating Perceptual Organization and Attention: A New Model For Object-Based Attention.

Jerzy P. Jarmasz (jjarmasz@ccs.carleton.ca)

Cognitive Science Program and Centre for Applied Cognitive Research,
Carleton University, Ottawa, Canada, K1R 7W9

Abstract

Recent research shows that, under certain conditions, visual attention is object-based. That is, attention preferentially selects objects in the visual field. These objects are processed, culminating in object recognition. On this formulation, the objects selected by attention are perceptual groups determined by the principles of perceptual organization of Gestalt psychology. These groups are formed independently of attentional processes and conceptual knowledge. This view is not consistent with available data about the visual system, which shows that perceptual organization is sensitive to conceptual information, depends on attentional processes, and infers representations that best explain the visual stimulus. Here, I propose a new account of visual attention that aims to correct these limitations of the Gestalt-based formulation. The nature of the object representations underlying perceptual and attentional mechanisms is discussed. It is proposed that attention and perception interact in an iterative process wherein constraints imposed both by the visual stimulus and an observer's cognitive set determine the "objects" to which attention is allocated. Thus, visual attention is object based precisely because it is intricately involved in perceptual organization, and not because it selects the output of perceptual organization, as is generally claimed. Experimental results that support the claim that attention influences perceptual organization are reviewed. Finally, the implications for human factors research and the metaphysics of everyday objects are discussed.

Introduction

Vision is generally assumed to have the functions of identifying, locating, and directing action towards objects (Solso, 1996). It is also assumed that the visual system requires attentional mechanisms to limit the amount of sensory information it processes (Fernandez-Duque & Johnson, 1999). Thus, awareness of objects in the environment is supposed to result from a series of processing stages that select sensory information and then construct representations of objects by extracting regularities from the visual stimulus and matching them to patterns in memory (Palmer, 1999).

It was first assumed that visual attention selects certain regions of the visual field, much the way a spotlight illuminates part of a stage and leaves the rest in the dark. Accordingly, this model is known as the spotlight model of visual attention (Fernandez-Duque & Johnson, 1999). On this model, attention is first directed to a region of the visual field, and only the information within that region is processed for object identification. This assumption was

questioned when researchers observed that people respond to visual features that belong to a single object more quickly and accurately than when the features belong to two objects (Duncan, 1984; Treisman, Kahneman & Burkell, 1983). Subsequent research confirmed that it is usually easier to process information within a single object than across objects (Lavie & Driver, 1996). These findings have led to the object-based model of visual attention (Duncan, 1984; Lavie & Driver, 1996). It is now generally recognized that the spotlight and the object-based models capture complementary aspects of visual attention (Driver & Baylis, 1998).

It is undeniable that information can be processed more readily within one object than across many (Lavie & Driver, 1996; Driver & Baylis, 1998). However, the object-based explanation for this difference in processing efficiency is problematic. Cognitive psychologists generally distinguish between spatio-temporally bounded physical objects and the mental representations of these objects. Physical objects correspond to what philosophers call concrete particulars (Loux, 1998), and will subsequently be referred to as c-objects. Similarly, the mental representation of visual objects will be henceforth referred to as p-objects (for "phenomenological" objects). The generally accepted story about object perception is that the visual system constructs p-objects, which represent c-objects via various perceptual and cognitive processes. Researchers who accept the object-based model contend that attention selects "objects" for further processing. Which objects are these – p-objects or c-objects? P-objects are supposed to be the end product of visual processing (Solso, 1996), so attention must presumably be engaged prior to the construction of p-objects. However, the alternate claim that attention directly processes c-objects themselves instead of sensory input is nonsense. Most researchers assume the visual system first constructs low-level representations of c-objects, based on the physical properties of the stimulus. These representations are then elaborated into p-objects by higher-order visual and conceptual processes (Hoffman, 1998; Palmer, 1999). These low-level representations will be referred to as a-objects (for "attentional objects"). The object-based model can be restated thus: Visual attention selects a-objects, which are passed on to higher visual processes for elaboration into p-objects, which are representations of c-objects.

Philosophers are actively studying the nature of c-objects (see Loux, 1998) and perceptual psychologists are

researching p-objects (e.g. see Biederman, 1995, and Kosslyn, 1995). But the notion of a-object implicit in object-based attention is still poorly defined. Most researchers take a-objects to be perceptual groupings based on the Gestalt principles of perceptual organization (Driver & Baylis, 1998), according to which observers perceive the details of a scene only as parts of global patterns. Perceptual organization was thought to conform to the general principle of figural goodness, or *Prägnanz* (Koffka, 1935). Figural goodness was exemplified in a number of specific principles (e.g., figure-ground, grouping by similarity, good continuation, closure, and common fate; Palmer, 1999). However, this view of a-objects is inadequate.

Cognitive scientists tend to assume that cognitive processing occurs in discrete stages, as first proposed by Sternberg (1969), until evidence forces them to think otherwise. Accordingly, researchers studying object-based attention have typically assumed that perceptual grouping, in the form of Gestalt grouping, occurs at a processing stage that is independent of, but feeds into, attentional processes, and that the product of attentional selection are independent of, but feed into, object recognition processes (Feldman, 1999). This view is problematic on two counts: first, the evidence that perceptual organization occurs prior to, and independently of, visual attention is not definitive. Second, the Gestalt account of perceptual organization itself has many shortcomings. Let us examine these two issues in turn.

Attention and Perceptual Organization

Mack, Tang, Tuma, Kahn and Rock (1992) and Rock, Linnett, Grant and Mack (1992) have presented results that suggest that perceptual organization does not occur without attention. They had participants perform a task that engaged their attention (typically, judging the relative length of the branches of a cross) while varying the background on which the main stimulus was displayed. Most trials had either a blank or a random background, but each participant also saw three (non-consecutive) trials where the background contained a 'critical stimulus', either a single shape or formed some Gestalt grouping. On the first critical trial, most participants reported not seeing the Gestalt grouping or not perceiving the shape or size of the lone object. On the second critical stimulus trial, participants were generally more successful in detecting the Gestalt group or the object. On third critical stimulus trial, participants were asked to report on the background stimulus only, generally with nearly perfect results.

Mack et al. (1992) and Rock et al. (1992) assumed that on the first critical stimulus trial, participants were not expecting to see anything of import in the background, and thus focused all of their attention on their primary task, whereas on the second and third critical stimulus trials, they implicitly allocated some or all of their attention to the background pattern. Accordingly, they interpreted their results to mean that perceptual organization cannot occur without attention. Ben-Av, Sagi and Braun (1992) reported

a similar study where participants had difficulty identifying background Gestalt groupings as their primary visual task became more demanding.

The results just discussed are not conclusive, however, as they cannot rule out that participants were merely unable to remember or encode the 'unattended' stimuli rather than failing to perceive them at all. Evidence along these lines is provided by Moore and Egeth (1997)¹. In a series of experiments, they had subjects judge the relative length of two parallel horizontal lines while varying the background. On half the trials the background consisted of random black and white dots, while on the other half, the background together with the two lines (now identical in length) formed the well-known Ponzo and Müller-Lyer illusions through the Gestalt principle of grouping by similarity. Participants reliably responded in a manner consistent with the illusions (i.e. reporting that the appropriate line was longer), even though the vast majority of them were not aware of seeing the background pattern. What is crucial here is that processing the background pattern is necessary for the illusion to influence participants' responses. The conclusion is that participants perceived the right background grouping even though they had no awareness of having done so.

Do the results of Moore and Egeth (1997) establish that perceptual organization does not require attention? Not necessarily. Moore and Egeth (1997) had each participant view the displays with the illusions 16 times while they performed the line-comparison task, whereas Mack et al. and Rock et al. tested their participants' awareness of the background patterns after only the first time each participant saw the pattern. It is possible that Moore and Egeth's participants learned implicitly and unconsciously that the background was informative and divided their attention between the primary and the secondary stimuli. Furthermore, they report that once the participants were aware of the Ponzo illusion, their performance of the line-judgment task dropped to chance levels, suggesting that the illusion was no longer effective (this pattern did not obtain with the Müller-Lyer illusion). Thus, for the Ponzo illusion at least, attention *does* play a role in perceptual organization.

Beyond Gestalt Grouping Principles

Taken together, the results from Mack et al. (1992), Moore and Egeth (1997) and Rock et al. (1992) suggest that attention can influence perceptual organization. Gestalt theory offers no way of accounting for this, as on this view perceptual grouping is largely determined by stimulus properties. Palmer (1999) and Pomeranz and Kubovy (1986) have pointed out further problems for the Gestalt view. First, the Gestalt principles don't distinguish between objects and groups of objects. Also, Gestalt principles ignore the role of top-down, general-purpose knowledge in perceptual organization. For instance, the Gestalt principles cannot explain why people who don't know that Figure 1 is

¹ I would like to thank the anonymous reviewer who brought this to my attention.

a picture of a Dalmatian usually fail to see any meaningful pattern in the image, whereas people who are aware that the image represents a dog not only find the dog easily but also organize the stimulus so that otherwise indistinguishable black dots become a dog, a sidewalk, and the shade beneath a tree.

Figure 1: Spot the Dalmatian!

In order to address these problems, an account of perceptual organization must do two things: it must show how perception and attention interact to form a-objects, and it must show how general-purpose conceptual knowledge can participate in the formation of a-objects without requiring full object recognition. Both of these objectives could be facilitated by construing perceptual organization as Inference to the Best Explanation (IBE), whereby where the visual system infers three-dimensional structures which best explain the retinal image (Hoffman, 1998; Leyton, 1992; Feldman, 1999)². IBE is an appealing account of human explanatory practice in general, but it suffers from the defect that explanatory 'goodness' has not yet been properly defined (Lipton, 1991). Nevertheless, vision researchers provide some candidates for goodness criteria in perceptual inference. Albert and Hoffman (1995), Feldman (1999), and Pomerantz and Kubovy (1986) have suggested that visual inference is overarchingly guided by the principle of genericity. That is, the visual system assumes, in the absence of other data, that the retinal image is a generic view of three-dimensional objects, rather than a very specific and "accidental" view of some other set of three-dimensional objects. A generic view is a two-dimensional projection of a three-dimensional structure that does not entail special or accidental circumstances in the projection. For instance, a straight line in the retinal image is a generic view of a straight edge in the environment, but would be a non-generic view of a curved edge that just happens to be seen head-on. The genericity principle can account for a large number of phenomena of perceptual organization. Furthermore, Pomerantz and Kubovy (1986) show that the Gestalt principles can and should be reinterpreted as instances of the genericity principle.

The notion of genericity can be extended to explain the role of conceptual knowledge in perceptual organization. Assuming an observer expects to see a Dalmatian in Figure

1, the splotches obviously form a generic view of the dog. Whereas, if the splotches corresponded to a horse, it would have to be either a typical horse seen under very specific shading conditions, or a strangely Dalmatian-like horse seen under normal viewing conditions. "Explaining" the image as that of a horse would require invoking a number of special circumstances, which interpreting the image as that of a Dalmatian does not. The visual system might thus limit the conceptual information involved in constructing a-objects to knowledge of generic views and expectations about which objects are present in a scene.

A-objects can now be re-defined: An a-object is a representation of the three-dimensional structure that best explains the two-dimensional retinal stimulus according to the genericity principle, which takes into account both physical stimulus properties and general-purpose conceptual knowledge.

Although the Dalmatian example demonstrates the role of semantic information in perceptual organization, it remains to be shown that a-objects as defined above actually play a role in object-based attention. The following section presents some recent experimental evidence bearing on this issue from our laboratory.

Recent Evidence for the Involvement of Attention in Perceptual Organization

A first line of evidence for the role of attention in perceptual organization comes from recent studies on object-based attention using moving stimuli (Jarmasz, 2001; Jarmasz, Herdman & Johannsdottir, in preparation). In these experiments, participants were shown a display consisting of two groups of identical dots. One set of dots was static, while the dots in the second group moved in unison in an elliptical trajectory that overlapped the location of the static dots. During each trial, two of the dots in the display changed color from light gray to one of two colors (either red and green, or blue and yellow). The target dots were located both in the static group, both in the moving group, or one in each group. Participants were required to determine whether the target dots were the same color. On some trials participants had to focus their attention on only one group of dots, while in other trials they had to spread their attention to the display as a whole, and avoid focusing on a specific group. When participants attended to the whole display, they responded significantly faster to target dots displayed within a single group than to targets appearing across both groups. The results were consistent with those found in the object-based attention literature using static displays (e.g. see Lavie & Driver, 1996; Treisman et al., 1983). However, when participants focused on only one of the groups, their responses were faster when both targets appeared in the attended group, and slowest when targets appeared either in the unattended group only or across groups. A comparison of response latencies across attentional focus conditions suggests that focused attention inhibits information processing of unattended stimuli rather than enhancing processing of attended stimuli relative to

²This does not necessarily imply deliberate, conscious inference.

situations where attention is deployed across the whole display. In all attentional focus conditions, both groups of dots overlapped in the display, so foveal limitation on visual acuity likely do not account for these results. Rather, they suggest that deliberate attentional allocation strategies influence the degree to which multiple perceptual groups are perceived as being separate from the others, or conversely as being part of a larger whole. This is consistent with the proposal above that a-objects depend on attentional factors as well as bottom-up stimuli properties.

A second line of evidence implicating attention in perceptual organization comes from a study using static visual objects (Jarmasz, 2002). In this study, participants were shown a display based on one used by Lavie and Driver (1996) consisting of two intersecting dashed lines. On each trial, two of dashes were replaced by two target elements, either a shorter dash or a gap (absence of a dash). The target elements could appear either near to each other on separate lines ('near' condition), far from each other on separate lines ('far' condition) or far from each other but on the same line ('object' condition). On half the trials, both dashed lines were the same color (either pink or yellow), whereas in the other trials each line was a different color. In all cases, participants responded most quickly to targets in the object condition, even though they were approximately seven times further apart in the object condition than in the near condition, thus replicating the effect found by Lavie and Driver (1996). When the dashed lines were of different colors, participants were equally slow in responding to targets in the near and far conditions relative to the object condition. However, when both lines shared a common color, participants responded more quickly to targets in the far condition than in the near condition (responses to targets in the object condition were still fastest overall). This suggests that in the same color condition, participants parsed the display either as two separate lines or as one large figure, depending on the location of the targets. These results further suggest that observers can implicitly acquire top-down attention allocation strategies that affect the perceptual organization of a stimulus from bottom-up cues (color & target location).

The two studies described above show that attention can be deployed, either implicitly or explicitly, so as to influence perceptual organization. The results of these two studies are inconsistent with the spotlight model of visual attention, in which spatial separation, but not shape, affects how quickly two stimuli are compared. However, the "standard" object-based attention model cannot account for these results either, as on this model perceptual grouping is assumed to be preattentive, and thus impervious to changes in attentional allocation strategies. An adequate account of visual attention and object perception will have to explain both how perceptual organization can affect attention (i.e. object-based attention) and how attention can affect perceptual organization. The next section presents such a model.

Towards a New Theory of Object-Based Attention

Current accounts of object-based attention do not reflect the reciprocal influences between attention and perceptual organization. Consequently, I propose a new account, the Inferential Attentional Allocation Model (IAAM; Jarmasz, 2001). Briefly, on this model attention and perceptual organization interact to incrementally build up representations of c-objects. Potential a-objects are constructed from regions of uniform color, luminance, and texture, and edge-bound surfaces in the visual stimulus (Palmer, 1999). These potential a-objects represent rival hypotheses as to the 3-D structures in the environment, and lack detail. A-objects are refined through cycles of grouping and selection (Grossberg, Mingolla & Ross, 1994). At each cycle, attention selects a-objects that best satisfy both genericity and cognitive set (i.e., an observer's perceptual expectations and general-purpose knowledge). This progressively liberates resources for generating more detailed a-objects that better "explain" the retinal image. If this process is interrupted before it culminates in stable a-objects, an observer may fail to perceive a c-object (Di Lollo, Enns, and Rensink, 2000, have found evidence for such a phenomenon). Figure 2 depicts these iterative processes.

The IAAM is a heuristic (i.e., exploratory) model. Even so, it allows for the following predictions: (1) stimulus-dependent, bottom-up information constrains possible a-objects in the scene, and as well as how much attentional resources the stabilization of particular a-objects will require; and (2) conceptual, top-down knowledge acts to determine which a-objects will eventually become stable and become p-objects. Thus, bottom-up properties of a stimulus should determine how "easy" it is to perceive certain objects, i.e., how much attention perceiving those objects will require and how efficient the processing will be. Top-down factors will sometimes push the visual system to organize a stimulus into more attentionally demanding configurations which will result in less efficient processing (reflected either in slower processing or more interference from other stimuli). The experiments reported above are largely consistent with these hypotheses. Common motion (a bottom-up factor) makes the segregation of a stimulus into distinct objects possible, but the intention to pick out one of these objects (top-down) enhances the processing of that object at the expense of processing information from other objects (Jarmasz, 2001; Jarmasz, Herdman & Johannsdottir, in preparation). Similarly, collinearity and common color (bottom-up) facilitate the segregation of two dashed lines into two objects, but implicit task demands (top-down) seem to determine whether the two lines are actually parsed as one large figure or two lines (Jarmasz, 2002).

Further work is needed to elaborate and test the IAAM. Namely, the notions of 'ease' of perceptual grouping and of efficiency of visual processing need to be operationally defined. Nevertheless, one can imagine how the IAAM

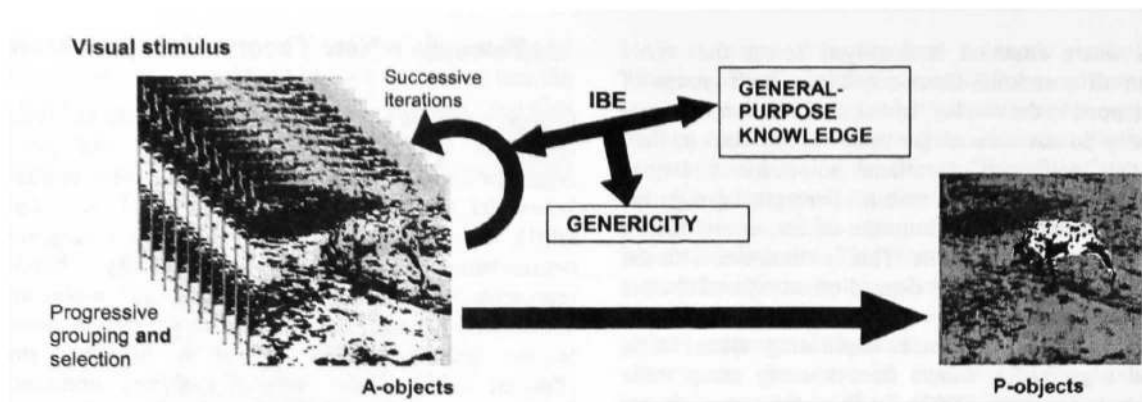

Figure 1: Grouping and selection processes in the IAAM

might apply to “real world” stimuli. For instance, if someone intends to move a box with a lid from a table to the top shelf of a bookcase, they will form a single a-object corresponding to the box and its lid. If, however, that person wants to open the box, they will form two a-objects, one for the lid and one for the box. On this view, a-objects are interest-relative; that is, a-objects depend on an observer’s goals and general-purpose conceptual knowledge, in addition to bottom-up stimuli. This is in contrast to the standard view, where a-objects are defined purely by stimulus properties.

Conclusion: Some Implications of the IAAM

The object-based model of attention is currently based on the assumption that visual attention selects perceptual groups that are formed preattentively according to the Gestalt grouping principles. This conceptualization of visual attention does not reflect the reciprocal influences between perceptual organization and attention, and further ignores the role of top-down information in perceptual organization. Moreover, this formulation is limited in its ability to guide human factors research, where broad principles are often lacking and problems often require ad-hoc solutions. A growing body of experimental evidence supports the notion that while attention is influenced by perceptual organization, it in turn influences whether and how perceptual organization occurs as well. Consequently, a new model of object-based attention, the Inferential Attentional Allocation Model, is proposed which attempts to capture the interaction between attention and perceptual organization. On this model, visual attention is object based not because attention selects objects, but rather because attention itself is indispensable to perceptual organization.

The IAAM is a heuristic model. In addition to providing a framework for developing a comprehensive account of visual attention, the IAAM also has potentially significant implications both for human factors research and for the metaphysics of concrete particulars. Regarding research on human factors, the IAAM shows that strategies for deploying attention interact both with visual stimuli and

with task demands. Thus, the design of graphical user interfaces such as desktop computer applications and head-up displays in aircraft and automobiles should take into account how a user’s cognitive and attentional sets might interact with the display.

The IAAM shows that what counts as an object for the visual system depends intimately on an observer’s goals and expectations. This reminds us that in a larger sense, everyday objects are embedded in a complex web of human activities and conventions. Standard metaphysical theories generally attempt to define concrete particulars without any reference to the agents that use and perceive them (e.g., see Loux, 1998). However, assuming that at least the broad lines of the IAAM are a valid account of object-based attention, what counts as an object for us as agents also depends on our expectations, intentions and general background knowledge. The criteria of “objecthood” might ultimately depend as much on epistemic issues as on metaphysical ones, as suggested by Smith (1996). Attention is object-based not only because attention and perceptual organization are mutually dependent, but also because objects would not be objects if we did not perceive them as such, but merely relatively coherent portions of the spatiotemporal flux we call the universe.

Abstract

Language provides an efficient, uniquely human way of transmitting non-obvious category information between individuals and across generations. To explore whether it can serve this purpose even for very young children, we conducted two experiments: one with 24-month-olds, and the other with preschoolers. Children made non-obvious inferences about perceptually misleading animals. Those who heard the animals called by counter-intuitive category labels made inferences different from those who did not hear the labels, demonstrating an important influence of language on thought, even at 24 months of age. However, preschoolers appear to have been less influenced than toddlers, suggesting that there are limits on children's willingness to accept anomalous category labels.

Introduction

Categorization is fundamental to human cognition, enabling communication and serving as the basis for the representation of objects and for predicting and explaining their behavior (Anglin, 1977; Markman, 1989). Children as young as 3.5 months (Eimas & Quinn, 1994), adults (Rosch et al., 1976), and non-human animals (e.g., Freedman et al., 2001) alike readily use perceptual similarity to determine the category to which something belongs. But when reasoning about an object, or explaining or predicting its behavior, perceptual appearance is not always criterial of category membership. For example, even though eels look like snakes, in order to more accurately characterize their ancestry, behavior and physiological processes, experts categorize them as fish.

Given sufficient experience, children as young as 30 months can form non-obvious categories by noting causal (Gopnik & Sobel, 2000) or functional (Kemler Nelson et al., 2000) regularities between objects. Under some circumstances, even non-human animals can learn to categorize objects in perceptually non-obvious ways (Herrnstein & DeVilliers, 1980). However, recognizing non-obvious similarities can be a slow and laborious process, often requiring experience that is difficult to obtain. Moreover, it requires every individual in every generation to have the experience for him or herself (Tomasello, 1999). Another, arguably more reliable and efficient way to obtain non-obvious category information is through language

(Gelman et al., 2000): When a trusted source uses an unexpected category label for an object, it reflects a particular perspective that others have found useful when thinking and reasoning about that object in the past, and it can cause us to revise a classification immediately. For language to have this effect, however, listeners may have to give up a compelling, perceptually based classification in favor of a classification they do not immediately understand.

As adults, we can accept linguistically provided non-obvious classifications (e.g., a whale is a mammal, not a fish) because we implicitly assume that something deeper than surface similarity binds category members together (Medin & Ortony, 1989). Such an essentialist assumption would facilitate the rapid uptake of non-obvious category terms. However, it is not clear whether very young children also expect categories and category terms to encode more than surface similarities. For example, it has been argued that children begin with or quickly develop an expectation that category labels encode similarly shaped objects (e.g., Imai, Gentner, & Uchida, 1994; Smith, 1999). Furthermore, whereas children readily learn words for basic-level categories (e.g., "table"), they have difficulty learning words for superordinate categories (e.g., "furniture"), which have fewer perceptual features in common than basic-level ones (e.g., Horton & Markman, 1980; Mervis & Rosch, 1981; Rosch et al., 1976). Finally, young children sometimes object to parental attempts to correct perceptually based categorization errors (Mervis, 1987).

In two studies, we investigated children's willingness to accept perceptually counter-intuitive classifications on the basis of linguistically provided information alone. In our first study, we asked this question of 24-month-olds. Gelman and her colleagues have found that children as young as 32 months can make inferences on the basis of linguistic information rather than perceptual appearance (Gelman & Coley, 1990; Gelman & Markman, 1986), but their procedure involves memory demands, verbal responses, and linguistic comprehension abilities beyond those of younger children. Our procedure uses an imitation paradigm that minimizes these task demands (see also Baldwin, Markman, & Melartin, 1993; Mandler & McDonough, 1996; Welder & Graham, 2001).

Although preschoolers have been shown to defer to adult labels in the face of perceptually inconsistent information (Gelman & Coley, 1990; Gelman & Markman, 1986), there must be limits on this process. Surprisingly, no one has considered situations under which children reject linguistically provided category information. Using the same paradigm and materials as in the first study, our second study takes up this question with preschoolers.

Experiment 1

Experiment 1 was designed to test whether 24-month-olds would use an experimenter-provided, sometimes counter-intuitive, category label when making non-obvious inferences. In particular, we were interested in whether they would use the label to make an inference that was different from the one they would make without a label.

Method

Participants Participants were 32 toddlers, ranging in age from 23 months, 6 days to 25 months, 28 days ($M = 24$ months, 10 days). Five additional toddlers were tested, but their data are not included due to extreme fussiness resulting in an inability to complete at least half of the session (4), or due to experimenter error (1).

Stimuli Eight animals from familiar categories were grouped into four sets based on similar sizes and body shapes: Cat-dog, horse-cow, bear-pig, and squirrel-rabbit. Category familiarity was confirmed by consulting the MacArthur Communicative Development Inventory for toddlers (Dale & Fenson, 1996), which indicated that at least 44% of 24-month-old children could produce the word associated with each animal (range: 43.9% for "squirrel" to 91.6% for "dog").

Realistic, color drawings of a typical exemplar of each animal were obtained from commercially available picturebooks, and were digitized for computer manipulation (hereafter, "standard animals"). In addition, three test animals for each set were generated on Adobe PhotoShop from the standard animals of that set: Two were typical exemplars (hereafter "typical test animals"), and were created by manipulating the coloration of the standards; the third test animal looked more like one standard animal than the other (hereafter, "misleading test animal"). Misleading test animals were created by using one of the standards (or an additional typical image) as a base, and adding features from the other standard image of that pair. Examples of standard and misleading animals from the cat-dog set are shown in Figure 1.

Sixteen graduate students rated each animal, including the standards, from each set on a 7-point continuum. At one end of the continuum was the category label for one of the animals in a given set (e.g., "cat"), and at the other end was the category label for the other animal in that set (e.g., "dog"). Subjects indicated on the continuum the position of each animal image, with 4 being ambiguous—exactly

Figure 1: Sample stimuli from the cat-dog set. Each stimulus set was made up of two standard animals, two typical animals (not shown, but very similar to the standards), and one of two misleading animals.

halfway between the two. The average ratings of the standards and typical test animals were always at the ends of the continuum (between 1 and 2 or between 6 and 7), and those of the misleading test animals were always slightly closer to the center, but leaning in one direction (between 2 and 3, or between 5 and 6) and significantly different from 4 and from each other. A full display of the stimuli and details of their adult ratings can be obtained at <http://www-psych.stanford.edu/~jaswal/Stimuli/index.html>.

All images were sized to approximately 3 to 4 inches wide, with their heights constrained by their widths. Each image (and its left-right reverse) was printed on a 600 dpi color printer, cut out, laminated, and mounted into a small stand that allowed it to remain upright.

Each set of animals was associated with a particular activity, and members of the same pair were associated with contrasting props or dioramas (hereafter, "props"). Activities were chosen that could be easily and clearly demonstrated with a 3-dimensional prop, and that might (though not necessarily) be familiar to children: The cat played with a ball of yarn, the dog played with a stick; the horse slept on the hay, the cow slept on the grass; the bear lived in the forest, the pig lived in the mud; the squirrel ate a nut, the rabbit ate a carrot. Props were purchased or specially constructed.

Design The 32 children were randomly assigned to a label or a no-label condition, resulting in 16 children per condition, balanced for sex. Each child in the label condition was yoked to a child in the no-label condition so that both saw exactly the same animals in exactly the same configuration and order. The only difference was that one heard a label during the presentation of each test animal, and the other did not.

Procedure Toddlers were seated on their parent's lap at a table in a testing room, or at a small table on their own, with the experimenter sitting across the table from them. Each session began with a warm-up trial to familiarize them with the procedure: The experimenter demonstrated that a fish lived in an aquatic scene ("water"), and a bird lived in a tree. They were then shown additional typical fish and birds in alternating order and asked to show where each lived, until they succeeded in putting a fish in the water and a bird in the tree consecutively, or until their attention waned. Correct selections were praised, and incorrect selections were corrected.

During the testing phase, children watched as the experimenter demonstrated and explained aloud that one standard animal engaged in an activity with one prop (for example, that a cat played with a ball of yarn), and that the second standard animal of that set engaged in an activity with another prop (for example, that a dog played with a stick). Following the introduction and labeling of each standard animal, children were encouraged to imitate the activity with that same animal.

Children were then shown the two typical test animals and one of the misleading test animals from that set, one at a time and in a random order. They were asked to show the activity in which each engaged. The children in the label condition heard the experimenter use a category label to introduce each of the test animals (for example, "Look at this! Look at this dog! Can you show me what this dog plays with?"). The typical test animals were always called by labels that matched their appearance, and the misleading test animals were always called by labels that were the opposite of their appearance (i.e., if adult raters had indicated that a misleading test animal looked more like a dog than a cat, it was referred to as "this cat"). To establish baseline levels, children in the no-label condition heard the experimenter use the phrase "this one" to introduce each test animal (for example, "Look at this! Look at this one! Can you show me what this one plays with?"). Regardless of their selection, children were given neutral feedback in a positive tone ("OK!"), and the experimenter then proceeded to the next test animal or animal set.

Most children were presented with all four sets of animals; however, due to fussiness, five children were presented with three sets rather than four. The order in which the animal sets were presented was counterbalanced across pairs of children according to a Latin Square design. The prop or diorama matching a misleading test animal's perceptual appearance appeared twice on the left and twice on the right for each child, and this was counterbalanced across pairs of children.

Coding was conducted off-line, via videotape, and involved noting which of the two possible props was selected for each test animal. Two coders, blind to condition, each coded one-half of the sessions. To assess reliability, each coder also independently coded 1/4 of the other coder's sessions (selected randomly); agreement on which prop was selected was 99% (Cohen's kappa=.98).

Results and Discussion

As shown in Figure 2, children in both the label and the no-label conditions inferred that the typical test animals engaged with the props associated with their perceptual appearance significantly more frequently than would be expected by chance (50%) [label condition: $t(15)=4.01$, $p<0.01$; no-label condition: $t(15)=2.93$, $p<0.05$], and at levels not different from each other [$t(30)<1$, *n.s.*]. This is consistent with other work showing that, in the absence of labels, even 9-month-olds can make non-obvious inferences based on an object's appearance (Baldwin et al., 1993).

When a test animal was perceptually misleading, however, labeling had a dramatic effect, as Figure 2 shows. Children in the label condition made inferences based on the perceptual appearance of the misleading test animals less frequently than by chance [$t(15)=-2.93$, $p<0.05$], whereas those in the no-label condition did so at chance levels [$t(15)<1$, *n.s.*]. A 2-way mixed ANOVA on the mean percentage of perceptual inferences (label/no-label \times typical/misleading) yielded a main effect of stimulus type [$F(1,30)=13.41$, $p<0.01$], and a significant interaction [$F(1,30)=6.62$, $p<0.05$]. Children in the label condition made significantly fewer inferences in line with the perceptual appearance of the misleading test animals than those in the no-label condition [$t(30)=-2.32$, $p<0.05$].

In short, children in the label condition inferred that the misleading animal engaged with the prop associated with its label, while those in the no-label condition were significantly more likely to infer that it engaged with the prop associated with its perceptual appearance. For example, when shown the misleading animal that adult subjects rated as dog-like, children who heard it referred to as "this cat" inferred that it played with the ball of yarn, while those who heard it referred to as "this one" were more likely to infer that it played with a stick.

Figure 2: Mean percentage of inferences by toddlers that were consistent with perceptual appearance. Error bars show standard error.

Using a non-verbal response measure, we found that even 24-month-old children weigh the category label that a speaker applies to an animal more heavily than the animal's perceptual appearance when the two are in conflict. Although the vast majority of category labels in a typical two-year-old's productive vocabulary represent categories whose members cohere perceptually (Samuelson & Smith, 1999), these children nonetheless expect category members to share deeper similarities, and they can use language to think about objects in non-obvious—even counter-intuitive—ways. The power of a simple category label to convey non-obvious category information may well develop with age and experience with language. Certainly by 24 months, however, this process is in place, and can serve as an important mechanism for the cultural transmission of knowledge and information.

This raises interesting questions about the limits of this process, including circumstances under which children might weigh an object's perceptual appearance more heavily than its category label. In our second experiment, we explored one possibility, namely that older children might be less willing to accept a perceptually counter-intuitive category label than younger children.

Experiment 2

Experiment 2 was designed to explore whether preschoolers would be as willing to accept perceptually counter-intuitive category labels as the toddlers in Experiment 1. Presumably, older children have been exposed both to more exemplars and to a wider range of exemplars from the familiar animal categories used in our experiment. Because of this experience, they may be less willing to accept anomalous category information. For example, when they see an animal clearly possessing the perceptual features of a dog (a "misleading test animal"), they may construe it as a dog that shares properties with other dogs—regardless of what the experimenter calls it.

Method

Participants Twelve 3-year-old ($M = 3$ years, 3 months; range = 2;10 to 3;6) of middle-class and upper-middle-class backgrounds participated at a university-affiliated preschool. Six were girls and six were boys.

Stimuli The stimuli were the same as those used in Experiment 1.

Design Experiment 2 used a within-subject design, with the same child hearing some test animals labeled and other test animals referred to as "this one."

Procedure Children were tested individually in a quiet room at their preschool. The procedure was generally the same as that used in Experiment 1: Children watched as the experimenter demonstrated and explained aloud that one standard animal engaged with one prop, and the second standard animal of that pair engaged with another. They

were then shown the three test animals one at a time and in a random order, and asked to show the activity in which each engaged. All children were shown four sets of animals.¹

The major difference from Experiment 1 was that children heard labels for test animals from two of the sets, and did not hear labels for test animals from the other two. As in Experiment 1, children were yoked in pairs so that both saw exactly the same stimuli in exactly the same configuration and order. When one child heard test animals from a particular set labeled, his or her yoked partner did not. The order in which the sets were presented was random, as was the order of the test-baseline sets. The prop matching the misleading animal's perceptual appearance appeared equally often on the left and right for label and no-label sets.

Coding was conducted off-line, via videotape, and involved noting which of the two possible props was selected for each test animal.

Results and Discussion

As shown in Figure 3, like the toddlers in Experiment 1, preschoolers inferred that the typical test animals engaged with the props associated with their perceptual appearance significantly more frequently than would be expected by chance, regardless of whether the animals were labeled or not [label condition: $t(11)=13.40$, $p<0.01$; no-label condition: $t(11)=6.09$, $p<0.01$], and at levels not different from each other [$t(11)=1.00$, $n.s.$].

For perceptually misleading animals that were not labeled, preschoolers had them engage with the prop that matched their appearance more frequently than would be expected by chance [$t(11)=11.00$, $p<0.01$]. By contrast, when they were labeled, children had them engage with the prop that matched their appearance at chance levels [$t(11)<1$, $n.s.$]. A 2-way repeated measures ANOVA on the

Figure 3: Mean percentage of inferences by preschoolers that were consistent with perceptual appearance. Error bars show standard error.

¹ Additionally, children were shown two sets of artifacts; those data will not be presented here.

mean percentage of perceptual inferences (label/no-label \times typical/misleading) yielded a main effect of condition [$F(1,11)=33.00, p<0.01$], a main effect of stimulus type [$F(1,11)=7.44, p<0.05$], and a significant interaction [$F(1,11)=23.44, p<0.01$]. When they heard misleading animals labeled, children made significantly fewer inferences in line with their perceptual appearance than when they did not hear them labeled [$t(11)=-5.61, p<0.01$].

As in Experiment 1 with toddlers, then, labeling clearly had an effect on preschoolers' inferences about the perceptually misleading animals. However, as will be discussed below, once performance on the typical animals was equated, preschoolers appear to have been less likely to accept and use counter-intuitive category labels than toddlers.

General Discussion

These two experiments investigated children's willingness to accept perceptually counter-intuitive classifications on the basis of linguistically provided information. In Experiment 1, 24-month-olds used category labels provided by the experimenter to make non-obvious inferences about animals that were the opposite of those they would make without a label. These results converge with those of Welder and Graham (2001), who found that 16- to 21-month-olds could use a label to make a non-obvious inferences about a novel object. In that study, infants who heard two moderately dissimilar novel objects called by the same novel name inferred that they shared a non-obvious property (Study 2). When the objects were not labeled, infants did not spontaneously assume that they shared the same property (Study 1).

Our design differs from that of Welder and Graham (2001) in an important way: In particular, whereas Welder and Graham used novel objects and novel labels (except in Study 3, where they used novel objects and familiar labels), we used instead familiar objects and labels. By using familiar categories, we were able to show that despite compelling, contradictory perceptual information indicating membership in a different category, 24-month-olds nonetheless could accept and use the experimenter's label in making a non-obvious inference.

In Experiment 2, we found that preschoolers could also use labels to make inferences different from those they would make without a label. This is consistent with work by Gelman and her colleagues (Gelman & Coley, 1990; Gelman & Markman, 1986), who have found similar results with preschoolers using different procedures. However, we also found that preschoolers were *less* willing to accept and use an unexpected category label than the toddlers in Experiment 1. The first piece of evidence for this conclusion comes from the chance analyses, which showed that hearing a label for a misleading animal made toddlers in Experiment 1 less likely than chance to make an inference in line with the animal's perceptual appearance, whereas preschoolers in Experiment 2 were merely at chance—meaning that the older children were as likely to

use the animal's perceptual appearance as the experimenter-provided label.

The second piece of evidence comes from an additional analysis of the data from the label conditions. So far, we have been considering the proportion of inferences children made in line with each test animal's perceptual appearance. Another way to consider the data from the label conditions only is in terms of the proportion of inferences children made in line with the experimenter-provided labels. These data are shown in Figure 4.

One might reasonably expect the proportion of label inferences for typical animals to be higher than the proportion of label inferences for the misleading animals, because in the case of a typical animal, there is no conflict between the label and the animal's appearance. And, in fact, as can be seen in Figure 4, for both toddlers and preschoolers, this is the case. However, whereas toddlers made only slightly fewer label inferences for misleading animals than typical ones, preschoolers were much less likely to make label inferences for misleading animals than typical ones. Indeed, a 2-way mixed ANOVA on the average percentage of label inferences (toddler/preschool \times typical/misleading) yielded a main effect of stimulus type [$F(1,26)=9.67, p<0.01$], and a significant interaction [$F(1,26)=7.01, p<0.05$]. In other words, toddlers were *equally likely* to make an inference in line with misleading animals' labels as typical animals' labels [$t(15)<1, n.s.$], while preschoolers were *significantly less likely* to do so [$t(11)=-3.74, p<0.01$].

Although differences in the design of these two studies make the cross-experiment comparisons somewhat tentative, this difference in children's willingness to accept anomalous category labels is extremely provocative: It suggests that 24-month-olds may be more "open-minded" about category information than 3-year-olds, perhaps because the toddlers assumed that they had not yet encountered all possible exemplars of even common

Figure 4: For toddlers and preschoolers who heard test animals labeled, mean percentage of inferences that were consistent with the labels. Error bars show standard error.

animals, whereas the preschoolers assumed they had (see Naigles, Gleitman, and Gleitman, 1992, for an analogous argument in verb learning). On-going work is considering this possibility.

Putnam (1977) has argued that a key element of adult communication is that we frequently use terms to refer to things without necessarily knowing the criteria for those terms. However, we assume that there are experts in our community who could provide the criteria and perform a test, if necessary, to fix the extension of those terms. In his words, language use requires a "division of linguistic labor." We have shown that children as young as 24 months also have something like a division of linguistic labor operating: They can accept and use what might be considered baffling category labels in order to make non-obvious inferences about animals. Using language in this way allows them to stretch the boundaries of their own spontaneously generated, often perceptually based, categories (but see Mandler & McDonough, 1996), and to take advantage of the richer and more conceptual frameworks that their cultures have evolved. A fruitful area for further investigation will be exploring the limits of this process.

Acknowledgments

We thank the children, teachers, staff, and parents who participated in this research, including those at the Arboretum Child Care Center and Bing Nursery School. Additionally, we thank A. Fernald for her assistance in subject recruitment and for providing testing space, and A. Sud for assistance in data collection. This research was supported by an NRSA predoctoral award from NIH and a Stanford Graduate Research Opportunity grant to VKJ.

Abstract

This paper presents a model of memory for multidimensional stimuli. The model captures the independence of features in memory, their recovery using spatial location and temporal cues, and the role of verbal recoding in building integrative feature memories. The model fits data showing that object features may be retrieved independently when given a location cue, but that correct retrieval of missing features given a feature cue depends on the correct retrieval of location. The model also suggests that positional codes implicated in many memory models may be the result of the initial positional encoding of stimuli by perception.

Introduction

Although perception appears to integrate multidimensional stimuli, mounting evidence suggests that object features, including color, form, motion, orientation, texture and location are independently processed by our visual system and can even remain independent in memory (e.g., Healthcote, Walker, & Hitch, 1994). This paper reviews the evidence for the independence and re-integration of features in memory and proposes a model of the spatio-temporal coding of memory for multidimensional stimuli. The model is implemented as a modification of the ACT-R cognitive architecture (Anderson & Lebiere, 1998) and shown to fit the results of a representative experiment.

Feature Independence in Memory

Evidence for the independent encoding of features in memory typically involves conjunction errors in recall or recognition tests (Reinitz, Lammers, & Cochran, 1992). In a recognition test, a conjunction error occurs when a subject reports previously seeing a new stimulus that consists of a conjunction of features from old stimuli. In a recall test, a conjunction error occurs when subjects recall a stimulus that erroneously conjoins features of previously seen stimuli. Conjunction errors have been demonstrated for a variety of stimuli, including faces (Reinitz et al., 1992; Treisman, Sykes, & Galade, 1977), two syllable nonsense words (Reinitz et al., 1992), colored forms (Stefurak & Boynton, 1986), and colored bars at different orientations (Isenberg, Nissen, & Marchak, 1990). Presentation times for study stimuli in these experiments range from 100 ms to several minutes, hence the results show that features are independently stored in both short- and long-term memory.

Nissen (1985) reported an experiment that suggested that visual features of objects (in this case color and shape) are stored separately, but are indexed or bound by their spatial location. Subjects were presented with four different shapes, each of a different color, and each in one of four positions, followed by either a location or color cue. When given a location or color cue, subjects were told to report the other two values indexed by that cue (color and shape, and shape and location, respectively). Subjects were tested in separate location-cue and color-cue conditions with 64 unique trials in each condition. Color, shape, location and cue were systematically randomized so as to ensure statistical independence among the stimuli and cues.

Nissen found that when the cue was a location, correct recall of color and shape were statistically independent; however, when the cue was a color, correct recall of shape depended on correct recall of location. These results suggest that object features are represented independently, with each feature associated with the object's spatial location. Thus, retrieving the shape of an object given its color as a cue requires one to first retrieve the location containing an object with that color, followed by retrieving the shape at that location.

Nissen's results showing independence in the location-cue condition were questioned by Monheit and Johnston (1994) who argued that because of the effects of guessing, very little deviation from independence was possible. By increasing the number of colors and forms (using letters instead of shapes) they reduced the effects of guessing and increased the expected deviation from independence. They also increased the number of trials to increase the chance of detecting a smaller deviation from independence. In a series of experiments that were similar to Nissen's location-cue condition, they found consistent evidence for the dependence of color and shape given a location cue. They explained their results by arguing that selective attention to an object tightly binds all features, but that in the Nissen experiment subjects have only enough time to selectively attend to a subset of the objects. Features of attended objects tend to be reported correctly, whereas features of unattended objects must be guessed. The combination of correct conjunction trials and those involving guessing produced the amount of dependence observed in their experiments.

Despite Monheit and Johnston's results, Nissen's experiment still supports a special role for location in binding object features. Monheit and Johnston's critique of

Nissen's experiment should apply equally well to the color-cue condition, meaning that it would have been just as difficult to detect dependence. However, Nissen found dependence in both the aggregate data and 8 of the 9 individual subjects. The fact that Nissen's experiment was sufficient to detect dependency in the color-cue condition suggests that location still plays an important role in binding object features. However, it is possible that selective attention may increase the association among object features, making location less important in the recovery of feature conjunctions. Indeed, Wolfe and Cave (Wolfe & Cave, 1999) suggested that pre-attentive features are loosely bound, whereas features of attended objects are more tightly bound.

Additional evidence suggests that features may also be bound by temporal cues (Treisman, 1977). In one experiment a series of several letters, a number, and several more letters were rapidly presented either at the same location or were alternated above and below the fixation point (Keele, Cohen, Ivry, Liotti, & Yee, 1988). Subjects were told to report the color of the background surrounding the digit. When the items were presented at the same location, more errors came from reporting the color of letters at the -1 and +1 temporal positions, items that appeared just before and just after the target. However, when the items were alternated among two locations, more errors came from the -2 and +2 temporal positions, items that occurred at the same spatial location as the target, but that were temporally more distant than the -1 and +1 items. Based on the results of several similar experiments, the authors argued that spatial contiguity is the dominant requirement for binding features and that temporal contiguity is of use only when features appear in the same location. However, the dominance of location may be an artifact of the task. Other researchers have argued that subjects may use multiple strategies to recover feature conjunctions, depending on the available cues at study and test (Heathcote, Walker, & Hitch, 1994).

There is also evidence that conjunction errors are affected by the distance and similarity among stimuli. Several experiments have found that subjects are more likely to erroneously conjoin features of adjacent or similar stimuli (for a review see Ashby, Prinzmetal, Ivry, & Maddox, 1996).

Other lines of research have shown that verbalization can result in an integrated stimulus memory. In a recognition task using colored animal shapes and long presentation times, Stefurak and Boynton (1986) demonstrated that subjects had memory for feature conjunctions unless they were prevented from naming study stimuli by engaging in a secondary verbal task, in which case they appeared to have absolutely no memory of feature conjunctions. In addition to suppressing verbalization, their experimental task provided neither temporal nor location cues, because the study stimuli were presented simultaneously, and the test stimulus was not presented in its study location. As a result, the suppressed verbalization condition did not provide any of

the cues (verbal, temporal, or spatial) that are thought to mediate feature integration.

Because verbalization appears to result in an integrated feature memory, it appears that verbal codes act in a different manner than spatial and temporal codes. Instead of acting as a tag for separate perceptual memories, it seems likely that the perceptual features are simply recoded as verbal cues. For example, the features "red" and "triangle" may be recoded as a verbal chunk "red triangle" that may be retrieved as a whole. Likewise, a display containing multiple stimuli may be recoded as a verbal list, such as "red triangle," "blue square" where each item is given a temporal position code.

To summarize, features of multidimensional stimuli appear to be represented independently in memory, but bound by temporal and spatial cues. Integrated feature representations are possible, but only if verbalization is possible.

ACT-R 5.0

Our model of feature integration in memory is embedded in the ACT-R 5 cognitive architecture (Bothell, 2002), where it adopts ACT-R's theory of memory and cognition (as described below), but slightly modifies ACT-R's perceptual system. This section describes ACT-R 5. Modifications needed to support the model are described in the next section.

Unlike previous versions of ACT-R, ACT-R 5 (hereafter called ACT-R) consists of several interacting, asynchronous modules for perception, cognition, memory, and action. The cognitive module consists of a procedural (production rule) long-term memory and a goal buffer that holds the current goal and goal-relevant information. The declarative memory module consists of declarative memory chunks and a retrieval buffer that holds the last item retrieved. Each declarative chunk has a unique identifier, a type, and zero or more attributes and values, such as:

Obj1 isa shape-map feature triangle location loc1

where "Obj1" is the identifier of the memory chunk, "shape-map" is the chunk type, "feature" and "location" are attributes, and "triangle" and "loc1" are their respective values.

The perceptual-motor module has subsystems for vision, hearing, speech production, and motor commands. The visual module has a buffer that holds the currently attended visual location and the visual stimulus at that location. It accepts commands from cognition (via production rules) to conduct visual search and shift visual attention. The motor module accepts commands from cognition to do simple computer-based physical tasks, such as moving the mouse to a certain location, pressing a mouse button, and typing commands.

Much of the coordination between perception and action is done by production rules. The condition side of a rule is limited to testing the buffers (including whether a particular

module is busy), whereas the action side can only initiate a limited set of actions that modify buffers or send commands to one of the other modules. When a rule fires, its action side initiates commands to the other modules, such as shifting visual attention or retrieving a red object from memory, after which the rule system is free to fire additional rules. The other modules in ACT-R handle these actions asynchronously, usually resulting (after some delay) in changes to the buffers. Rules can then detect these changes and take appropriate actions. Although more than one rule can match at a given time, ACT-R only fires one rule in each cycle. A psychologically realistic conflict-resolution mechanism, based on cost and probability of success, determines which of several matching rules will fire.

To understand how this works, suppose that ACT-R is given a cued recall task, where it must report a remembered shape with a cued color. Furthermore, assume that ACT-R is attending to a fixation point that changes to the cue word "red." When the visual system detects the change, it updates the visual buffer to indicate that the word "red" is now attended. A production rule that is conditioned on seeing a word in the visual buffer fires and initiates a memory recall request for a red shape, plus notes on the goal that such a request was initiated. As the declarative memory module begins to process this request, the rule system continues to check for and fire any matching rules. This allows ACT-R to engage in additional cognitive processing, including initiating commands to the perceptual-motor system, while the memory system processes the retrieval request. When the retrieval request is complete, the retrieval buffer is filled with either the newly retrieved chunk or an indication of a retrieval failure. Two separate rules, both sensitive to the goal annotation indicating the retrieval request, handle these possibilities. One rule tests for a shape in the retrieval buffer and initiates a speech command to say the name of the shape, the other rule tests for a retrieval failure and initiates a second retrieval to guess a shape.

To understand the model presented below, it is also necessary to understand how ACT-R processes retrieval requests. Retrieval requests specify a chunk type and one or more attribute-value pairs. The memory module returns the chunk of the specified type with the highest activation value, where activation of chunk i is determined by

$$A_i = B_i + \sum_j W_j S_{ji} + \sum_k P_k M_{ki} \quad (\text{EQ 1})$$

B_i is the base level activation of the chunk, reflecting how recently and frequently it has been retrieved. The first summation reflects associative priming of the chunk by chunks in the goal buffer, where W_j is the available activation and S_{ji} is the strength of association from chunk j to chunk i . W_j is typically set to $1/n$, where n is the total number of chunks in the goal buffer. S_{ji} is initially set to $S/\ln(n)$, where S is a constant and n is the number of chunks that have chunk j as an attribute value. This setting produces the classic fan effect (Anderson, 1974).

The second summation in EQ 1 reflects similarity of the chunk i to the retrieval cue. M_{ki} is the similarity between the

value of the k th attribute in the retrieval cue and the value in the corresponding attribute of chunk i . P_k (which defaults to 1) reflects the weighting given to the similarity of attribute k . By default, M_{ki} is 1 if the k th attribute value in the cue is identical to the corresponding value in chunk i , otherwise it is -10.

To model the random fluctuations of human memory, activations vary with time by adding noise as a logistic function of the parameter s , where s is related to the variance of the noise by

$$\sigma^2 = \frac{\pi^2}{3} s \quad (\text{EQ 2})$$

Finally, the activation threshold τ specifies the minimum activation value for retrieving a chunk. If all chunks matching the cue fall below this value, the retrieval request fails. As with chunks, the retrieval threshold varies from time to time according to the noise parameter s .

The approximate probability of retrieving a chunk i given k competitors (including the threshold and chunk i) is given by

$$P(i) = \frac{e^{A_i/s\sqrt{2}}}{\sum_k e^{A_k/s\sqrt{2}}} \quad (\text{EQ 3})$$

where A_n is the mean activation of chunk n .

A Model of Memory for Multidimensional Stimuli

The model assumes that attending to a multidimensional stimulus results in a set of feature chunks in memory, where each chunk encodes one feature along with one or more temporal and spatial tags. While attention is fixed on the stimulus these chunks also appear in the corresponding perceptual buffer. If a stimulus is recognized (either identified or classified or both), perception may also deliver a separate chunk encoding the identity (or class) of the stimulus along with spatial and temporal tags.

Suppose that ACT-R attends to a red square at location Loc22 on a computer screen at time $t1$. ACT-R's visual buffer is then filled with chunks encoding red at Loc22 $t1$, square(shape) at Loc22 $t1$, and square(class) at Loc22 $t1$. These same chunks are also added to ACT-R's declarative memory. This is shown graphically in Figure 1, where squares represent chunks and arrows indicate chunk attributes. Locations (e.g., loc22) are chunks that correspond to unique locations using the computer-screen as the frame of reference.

A spatial tag encodes where the feature occurs and may be given in any number of frames of reference (e.g., Wang, Johnson, Zhang, 2001). For instance, one spatial tag might give object heading and distance in egocentric (body-centered) coordinates, whereas another spatial tag might indicate the exocentric heading and bearing of the object from another object. Because ACT-R's perceptual-motor

system is designed to work with two-dimensional computer displays, the model provides a spatial tag relative to the frame of the display. Evidence for frame-relative location encoding has been found in both monkeys and humans. Rolls (1999) found that some neurons in the monkey hippocampus responded to where the monkey looked on a screen independent of the position of the monkey relative to the location of the screen. Hock, et al. (1989) showed that subjects unintentionally retained frame-relative locations of circles forming patterns in a frame, such that they could estimate the frequency with which circles appeared at a particular location within the frame.

Given enough time, rules may recode the features. For instance, a set of rules may verbalize the visual features "red" and "triangle" resulting in a redundant verbal code with appropriate temporal tags. Rules may also recode the features into an integrated representation, such as a single chunk that binds "red" and "triangle." Whether or not a stimulus is recoded, and the nature of the recoding, is dependent on the production rules, which in turn depend on the current goal and the strategy being used to achieve it.

Figure 1. Representation of color, shape and location in the ACT-R model. Temporal cues are not shown.

The model assumes that the similarity (M in EQ 1) of temporal and spatial tags is inversely proportional to their temporal and spatial distance; however, the exact nature of this relationship is left to the model builder. As a result, the model will tend to confuse spatially adjacent features.

Applying the Model to the Nissen Task

As a partial test of the model, we applied it to the Nissen (1985) experiment described earlier. The critical phenomena in this experiment is that recall of color and shape is independent given a location cue, but when given a color cue, recall of shape is dependent on correct recall of location.

The ACT-R model contains production rules for attending to the four colored objects, attending to the cue, retrieving the answers, and pressing keys to record its responses. When presented with the 4 objects, the model visually attends to each object, resulting in automatic encoding of a color-map and shape-map chunk for each object. It then waits for the cue to appear, at which point it attends to the cue and begins the retrieval and response process.

The critical production rules for modeling the experimental results are those for retrieving location given a color, and those for retrieving color and shape given a location. When given a location cue the model first attempts to retrieve a chunk encoding the color at that location (such as obj1c in Figure 1), and then attempts to retrieve a chunk encoding the shape at the given location (such as obj1a). When given a color cue, the model attempts to retrieve a color-map chunk containing that color (e.g., obj1c). It then uses the location in this chunk to retrieve a chunk encoding the shape at that location.

If a rule fails to retrieve a chunk, the model will guess an appropriate value. For example, if the model fails in retrieving a color-map chunk with color red, it will simply guess a location, and then use that location when it attempts to retrieve the shape.

Fitting the Nissen data requires estimating the parameters in EQ 1, as well as the activation threshold, and the noise parameter. The activation threshold and the base level activation B_i for all stimulus chunks were set at 0—the default value. The amount of activation available for associative priming was also set at 0, because chunks in the goal buffer are redundant with attribute values in the retrieval cue. Similarity among matching attribute values, including locations, was set to 1 with mismatching values set to 0. The noise parameter s was the only parameter tuned to fit the data. We used EQ 3 and the results from the Nissen experiment to determine an initial value of s , then iteratively refined it over several model runs to produce the fit reported below (where $s = 0.39$).

A. Location-Cue Condition

		Shape		
		Correct	Incorrect	
Color	Correct	0.485 (0.450)	0.212 (0.219)	0.697 (0.669)
	Incorrect	0.213 (0.175)	0.090 (0.156)	0.303 (0.331)
		0.698 (0.625)	0.302 (0.375)	

B. Color-Cue Condition

		Shape		
		Correct	Incorrect	
Location	Correct	0.477 (0.494)	0.221 (0.234)	0.698 (0.728)
	Incorrect	0.032 (0.051)	0.271 (0.221)	0.303 (0.272)
		0.509 (0.545)	0.492 (0.455)	

Figure 2: Results of simulating 50 subjects for each condition. Values in parentheses are the experimental results from Nissen.

The results of running the model for 50 subjects in each of the two conditions are shown in Figure 2 along with the Nissen data. As expected, shape and color recall are statistically independent in the location-cue condition ($\chi^2 = 0.131$, $p = 0.72$), whereas location and shape are dependent in the color-cue condition ($\chi^2 = 901.23$, $p < 0.01$). The proportions of correct and incorrect recall across both conditions produce a good fit to the Nissen data: $R^2 = 0.95$.

Conclusion

The model described in this paper can account for the basic phenomena of memory-based feature integration. The special role of location was demonstrated by applying the model to the Nissen task. The use of temporal cues, such as that reported by Keele, et al. and discussed earlier, is supported by the model's use of temporal tags for each feature. If location is given a stronger association to the features than is the temporal tag, this would produce Keele's results showing a role of temporal contiguity only for items that appear in the same spatial location. The tendency to erroneously conjoin spatially adjacent features and features of similar stimuli is captured in the model using ACT-R's theory of memory retrieval which tends to confuse similar stimuli (see the discussion of EQ 1). This means that features of spatially proximal objects will be confused more often than those of spatially distant objects. It also means that if the model is trying to recall the color of an oval, it would be more likely to confuse its color with that of a circle than with a square.

The effects of recoding, including verbalization, are captured in the model by assuming that the names of individual features or the name or semantic identity of an object may be memorized instead of the individual visual features. If there is enough time for object identification, the subject need only remember an object's identity and location during study. At test, the object's identification provides a cue for reporting essential object features. Such recoding will produce integrated memories, because the individual features are already well-learned and "bound" to the object identity. If a subject remembers seeing a banana, conceptual knowledge of bananas is sufficient to recall that it was yellow and crescent shaped—there is no need to encode the specific perceptual features in a new memory trace.

Such a strategy will not work, however, if the task presents bananas in unnatural colors. In this case, verbal rehearsal and the resulting verbal memory may be of use. For instance, given enough time a subject might remember objects in the Nissen task by verbally rehearsing "red triangle, blue square..." and so on. Recall of these items would then be subject to serial recall effects, such as the serial position curve and positional errors. It seems likely that such a strategy would result in fewer conjunction errors, which would explain why verbalization results in integrated feature memory.

The model provides a possible explanation for the need to use positional codes (instead of integrated codes or associative chaining) in cognitive models of memory tasks.

Positional codes were used to account for chunk position effects in alphabetic retrieval response times (Klahr, Chase, & Lovelace, 1983) and positional errors in serial recall (Anderson, Bothell, Lebiere, & Matessa, 1998). It is possible that these codes may be the direct result of the positional (temporal or spatial) encoding of stimuli by perceptual processes.

One limitation of the model is that it treats all errors as memory retrieval errors. However, the model could be extended to include probabilities for correctly perceiving features, or a theory of feature perception. However, since our emphasis is on the representation of features in memory and their later reintegration, we saw no need to introduce additional theory.

Monheit and Johnston's demonstration of dependence of color and shape given a location cue provides a challenge to the model presented here. To account for the dependence our model must be modified to provide for some strength of association between features of attended objects. In the present model, knowing the color of an object does not activate the object's shape (e.g., the strength of association between color and shape, S_{ji} in EQ 1, is 0). In the revised model, the color of a previously attended object would activate its shape, allowing for some dependence among features of objects. This would make our model consistent with Wolfe and Cave's view that preattentive features are loosely bound, whereas features of objects that have been attended are more tightly bound.

Finally, the model is meant to provide a foundation for a comprehensive theory of spatial cognition embedded in ACT-R. By embedding the model in ACT-R other researchers can use it in their models, where it may provide additional constraints and enable more realistic memory representations and behavioral predictions.

Abstract

This paper presents a formalisation and analysis method for the dynamics of a reasoning process in which multiple representations play a role. Dynamics of reasoning processes are described by reasoning traces consisting of sequences of reasoning states over time. Reasoning states have a compositional structure; they are composed of different parts, for example, for different representations. Transitions between two reasoning states model reasoning steps. In relation to the compositional structure of the states, transitions are classified into a number of types. An example reasoning process involving multiple representations is used to illustrate how its dynamics can be formalised and analysed using the approach.

Introduction

Within Cognitive Science in recent years the dynamical perspective on cognitive phenomena has been emphasized and received much attention. In most literature focussing on the dynamics of cognition, the Dynamical Systems Theory (DST) is taken as a point of departure; e.g., (Port and Gelder, 1995). This theory assumes that, in contrast to the use of symbolic representations, modelling and analysis of dynamics of cognitive phenomena can be done more effectively by using representations based on real numbers and mathematical techniques, in particular difference and differential equations. The convincing examples illustrating the usefulness of this perspective often address lower level cognitive processes such as sensory or motor processing. Indeed one of the advantages of the Dynamical Systems Theory is that it is able to model the temporal aspects of events taking place on a continuous time scale, such as, for example, recognition time, response time, and time involved in motor patterns and locomotion.

Also some examples of higher level cognitive processes have been addressed using DST; for example the dynamic models for decision making developed by Busemeyer and Townsend (1993). Especially the continuous adaptive aspects of the decision making are covered nicely in this approach. Areas for which the quantitative approach based on DST is assumed to have less to offer are the dynamics of higher level processes with mainly a qualitative character, such as certain capabilities of language processing and reasoning. In the last two decades, within the areas of Computer Science and Artificial Intelligence alternative techniques have been developed to analyse the dynamics of phenomena using qualitative means. Examples are process algebra; transition systems; dynamic and temporal logic;

event, situation and fluent calculus; e.g., (Eck, et al. 2001; Hölldobler and Tielscher, 1990; Kowalski and Sergot, 1986; Reiter, 2001). Just as difference or differential equations, these alternative techniques allow to consider and relate states of a process at different points in time. The form in which these relations are expressed can cover both quantitative and non-quantitative aspects. This paper illustrates the usefulness of such an approach for the analysis and formalisation of the dynamics of reasoning. Here a broad perspective is taken on reasoning, subsuming, for example, reasoning involving multiple representations.

A formal analysis method for the dynamics of reasoning is presented and illustrated by an example reasoning pattern involving geometric and arithmetic representations. This pattern is analysed and characterised in terms of a set of dynamic properties. The properties have been formalized, thus enabling automated support of analysis by an analysis environment that has been developed.

Below, first the dynamic perspective on reasoning is discussed in some more detail. Next, the example reasoning pattern is introduced, and the first steps of an analysis are made. Third, a number of dynamic properties identified for the example reasoning pattern are presented. Finally the analysis method is summarised and the contribution of the research presented in the paper is discussed.

Reasoning Dynamics

Analysis of the cognitive capability to perform reasoning has been addressed from different areas and angles. Within Cognitive Science, the two dominant streams are the syntactic approach (based on inference rules applied to syntactic expressions, as common in logic), e.g., (Rips, 1994), and the semantic approach (based on construction of mental models); e.g., (Johnson-Laird, 1983; Yang and Johnson-Laird, 1999).

Reasoning steps in natural contexts are usually not restricted to the application of logical inference rules. For example, a step in a reasoning process may involve translation of information from one representation form (e.g., geometrical) into another one (e.g., arithmetical). Or, an additional assumption can be made, thus using a dynamic set of premises within the reasoning process. Decisions made at specific points in time during the process, for example, on which representations to use or which assumptions to make, are an inherent part of the reasoning. Such reasoning processes or their outcomes cannot be

understood, justified or explained without taking into account these dynamic aspects.

To formalise the dynamics of a reasoning process, traces are used. Reasoning traces are time-indexed sequences of reasoning states over a time frame; for stepwise reasoning processes the set of natural numbers as a time frame is an appropriate choice. The set of all possible reasoning states defines the space where the reasoning takes place. Reasoning traces can be viewed as trajectories in this space, for which every (reasoning) step from one reasoning state to the next one is based on an *allowed transition*. If the possible reasoning states and the allowed reasoning steps or transitions are characterised, the set of proper reasoning traces can be defined as the set of all possible sequences of reasoning states consisting only of allowed transitions.

Reasoning States

A reasoning state formalises an intermediate state of a reasoning process. The content of such a reasoning state usually can be analysed according to different aspects or dimensions. For example part of the state may contain a geometric representation, another part an arithmetic representation. Accordingly, the reasoning state is structured as a composition of (i.e., a tuple of) a number of parts, indexed by some set I . This index set includes different aspects or views taken on the state, e.g., $I = \{\text{geometric}, \text{arithmetic}\}$. The set of reasoning states RS can be characterised as a Cartesian product $RS = \prod_{i \in I} RS_i$ where RS_i is the set of all states for the aspect indicated by i . For example, $RS_{\text{geometric}}$ may denote the set of all possible geometric representations; note, however, that it is also possible to use more dimensions, e.g., different types of geometric representations can be formalised. This Cartesian product formalises the multi-dimensional space where the reasoning takes place. For a reasoning state, which is a vector $s = (s_i)_{i \in I} \in RS$ in this space, the s_i are called its *components*.

Reasoning Steps: Transitions of Reasoning States

A transition from one reasoning state to another reasoning state, i.e., an element $\langle s, s' \rangle$ of $RS \times RS$, formalises one *reasoning step*; sometimes also denoted by $s \rightarrow s'$. A *reasoning transition relation* is a relation on $RS \times RS$. Such a relation can be used to specify the *allowed transitions*. Transitions differ in the set of components that are involved. The most complex transitions change all components of the state in one step. However, within stepwise reasoning processes, usually transitions only involve a limited number of components of the state, e.g., only one or two. Transitions can be classified according to which set of components is involved. The most simple types of transition involve a single component transition. Next come transition types where two components are involved. In the current approach we concentrate on these two classes of transition types.

Single component transition types

For example, when a modification in the reasoning state is made solely within a geometric representation, only the geometric component of the state changes (geometric

reasoning step). Or, if a calculation (arithmetic reasoning) step is performed, only the arithmetic component is changing. These single component transitions involve only that component and can be defined within one component only:

$$\begin{array}{l} \text{geometric} \rightarrow \text{geometric} \\ \text{arithmetic} \rightarrow \text{arithmetic} \end{array}$$

It is also possible that one component of a state is changed by information acquisition, importing information from an external source in the reasoning process.

Transitions involving two components of a reasoning state

Other types of transitions involve more than one component. For example, if information from a geometric representation is translated into an arithmetic form, thereby extending the arithmetic representation, then two components of the state are involved: the arithmetic component and the geometric component. Examples of transition types involving two components are:

$$\text{geometric} \times \text{arithmetic} \rightarrow \text{geometric}$$

(e.g., the geometric representation is extended or modified with results from the arithmetical representation)

$$\text{arithmetic} \times \text{geometric} \rightarrow \text{arithmetic}$$

(e.g., the arithmetic representation is extended or modified with results from the geometrical representation)

Reasoning Traces

Reasoning dynamics results from successive reasoning steps, i.e., successive transitions from one reasoning state to another. Thus a *reasoning trace* is constructed: a time-indexed sequence of reasoning states $(\gamma)_t \in T$, where T is the time frame used (the natural numbers). A reasoning trace can be viewed as a trajectory in the multi-dimensional space $RS = \prod_{i \in I} RS_i$ of reasoning states. An example of such a reasoning trace will be discussed in Section 3; see also Figure 1. Reasoning traces are sequences of reasoning states subject to the constraint that each pair of successive reasoning states in this trace forms an allowed transition. A trace formalises one specific line of reasoning.

Example Reasoning Process

An example multi-representation reasoning process is used to illustrate the approach put forward: interaction between arithmetical reasoning and geometrical reasoning. The example focuses on how to determine the outcome of multiplications such as 23×36 . Experiences on using such processes with children (8-9 years old) in class rooms have been reported, e.g., by Dekker et al. (1982), see also (Hutton, 1977). The example can also be extended to an example for children of 13 or 14 years to support algebra by geometric visualisations, e.g., the algebraic identity $(a+b)^2 = a^2 + 2ab + b^2$ interpreted as the area of a partitioned square of $(a+b) \times (a+b)$ in relation to areas of its parts: a square of $a \times a$, a square of $b \times b$, and two rectangles of $a \times b$. Also teaching quadratic equations can be supported by such visualisations as discussed, e.g., by Bruner (1968), pp. 59-63. The example pattern shows two types of one component transitions of reasoning states, and two transition types involving two components:

- an *arithmetical* reasoning step: arithmetic \rightarrow arithmetic
- a *geometrical* reasoning step: geometric \rightarrow geometric
- a *translation* of an arithmetical representation into a geometrical representation: geometric \times arithmetic \rightarrow geometric
- a *translation* of a geometrical representation into an arithmetical representation: arithmetic \times geometric \rightarrow arithmetic

The idea is that only simple arithmetical steps are required. The more complicated steps are performed via the geometrical representation. A number of skills are assumed. These skills can be defined in the form of transitions.

A. Assumed arithmetic skills arithmetic \rightarrow arithmetic

- aa1. splitting a number in 'tens' and single digits: $28 = 20 + 8$
- aa2. addition of a list of numbers of up to 4 digits, such as $1200 + 340 + 120 + 6$
- aa3. multiplication of two numbers starting with a nonzero digit, followed by zero or more zeros, such as 20×8 , 60×30 .

B. Assumed geometric skills geometric \rightarrow geometric

- gg1. partitioning a rectangle in non-overlapping areas based on partitionings of its sides
- gg2. determining the area of a figure from the areas of a (non-overlapping) partition

C. Assumed translation skills

geometric \times arithmetic \rightarrow geometric:

- ag1. drawing a rectangle with arithmetically given dimensions
- ag2. partitioning a line segment according to a splitting of its length
- ag3. determining the area of a rectangle from the multiplication of the lengths of its sides

arithmetic \times geometric \rightarrow arithmetic:

- ga1. translating the area of a rectangle into the multiplication of the lengths of its sides
- ga2. translating the area of a combination of nonoverlapping areas into the sum of the areas

Figure 1: Reasoning trace as a trajectory in a two-dimensional reasoning state space.

The example reasoning trace, based on class room observation (cf. Dekker et al., 1982), forms a trajectory in the two-dimensional reasoning state space

$$RS = RS_{\text{arithmetical}} \times RS_{\text{geometrical}}$$

This trajectory is depicted in Figure 1. Note that in this Figure only the changing component is visualised by an arrow, not what component affected this change. Therefore, e.g., both a geometric reasoning step and a translation of an arithmetic into a geometrical representation are depicted by a vertical arrow. The detailed trace is presented below.

Starting problem What is the outcome of the multiplication 23×36 ?

Step 1 ag1 representation translation

Create a rectangle of 23×36 .

Step 2 aa1 arithmetic reasoning

Split the numbers into the 'tens' and single digits: $23 = 20 + 3$; $36 = 30 + 6$

Step 3 ag2 representation translation

Translation of the arithmetical splitting of the numbers into partitions of the sides within the geometrical representation.

Step 4 gg1 geometric reasoning

Partition the area of the rectangle according to the partitioning of the sides.

Step 5 ga1 representation translation

For each part identify the corresponding arithmetical expression for its area: 20×30 , 20×6 , 3×30 , 3×6

Step 6 aa3 arithmetic reasoning

Determine the outcomes of the four multiplications $20 \times 30 = 600$; $20 \times 6 = 120$; $3 \times 30 = 90$; $3 \times 6 = 18$

Step 7 ag3 representation translation

Identify the areas of the parts of the rectangle based on the outcomes of the multiplications.

Step 8 ga2 geometric reasoning

Assert that the area of the rectangle as a whole is the combination of the areas of the parts

Step 9 ga2 representation translation

Identify the corresponding arithmetical relation: $600 + 120 + 90 + 18$

Step 10 aa2 arithmetic reasoning

Calculate the sum: $600 + 120 + 90 + 18 = 828$

Dynamic Properties

To specify properties on the dynamics of a reasoning process, the temporal trace language TTL used by Herlea et al. (1999), and Jonker and Treur (1998) is adopted. This is a language in the family of languages to which also situation calculus (Reiter, 2001), event calculus (Kowalski and Sergot, 1986), and fluent calculus (Hölldobler and Tielscher, 1990) belong. In short, in TTL it is possible to express that in a given trace at a certain point in time the reasoning state has a certain (state) property. Moreover, it is possible to relate such state properties at different points in time. As an example, the following (global) property of a reasoning trace γ is considered, which expresses that all multiplication problems in two digits eventually will be solved.

GPI

at any point in time t

if in the reasoning state in trace γ at t an arithmetic representation of a multiplication problem for numbers x and $y < 100$ is present,
then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' an arithmetic representation of a solution z of this multiplication problem with $z = x \cdot y$ is included.

The formalisation of this property in TTL is as follows.

$$\begin{aligned} \forall t \forall x, y < 100 \text{ state}(\gamma, t, \text{arithmetic}) \models \text{multiplication_problem}(x, y) \\ \Rightarrow \exists t' \geq t \exists z \ z = x \cdot y \ \& \\ \text{state}(\gamma, t', \text{arithmetic}) \models \text{is_solution_for_multiplication_of}(z, x, y) \end{aligned}$$

Note that for simplicity no maximal allowed response time has been specified. If desired, this can be simply added by putting a condition $t \leq r$ in the consequent with r the maximal response time.

Milestone Properties

Within the overall reasoning process a number of milestones can be defined, and properties can be identified that express whether the process from one milestone to another one has been performed properly. Apart from the start and the finish, two intermediate milestones were defined: a reasoning state in which the problem has been represented in a geometric representation and it has been decomposed geometrically (after step 4 in the example trace), and a reasoning state in which a geometric representation with numbers in the areas occurs, i.e., in which the subproblems have been solved (after step 7 in the example trace). Accordingly, the following milestone properties have been formulated.

MP1

at any point in time t
if in the reasoning state in trace γ at t an arithmetic representation of a multiplication problem for numbers x and $y < 100$ is present,
then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' a geometric representation of a rectangle ABCD is included with points P on AB and Q on AD , with $|AB| = x$ and $|AD| = y$
and this rectangle is partitioned into four areas $A_{11}, A_{12}, A_{21}, A_{22}$ by two lines $PP' \parallel AD$ and $QQ' \parallel AB$ with P' on CD and Q' on BC with $|AP| = x_1$, $|PB| = x_2$, $|AQ| = y_1$, and $|QD| = y_2$, where x_1, y_1 is the 10-part of x , resp. y , and x_2, y_2 is the digit part of x , resp. y .

Here, $|AB|$ is the length of AB , and \parallel is 'in parallel with'.

MP2

at any point in time t
if in the reasoning state in trace γ at t a geometric representation of a rectangle ABCD is included with points P on AB and Q on AD , with $|AB| = x$ and $|AD| = y$,
and this rectangle is partitioned into four areas $A_{11}, A_{12}, A_{21}, A_{22}$ by two lines $PP' \parallel AD$ and $QQ' \parallel AB$ with P' on CD and Q' on BC with $|AP| = x_1$, $|PB| = x_2$, $|AQ| = y_1$, and $|QD| = y_2$, where x_1, y_1 is the 10-part of x , resp. y , and x_2, y_2 is the digit part of x , resp. y ,
then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' in each of these areas A_{ij} a number z_{ij} is represented which equals $x_i \cdot y_j$.

MP3

at any point in time t
if in the reasoning state in trace γ at t a geometric representation of a rectangle ABCD is included with $|AB| = x$ and $|AD| = y$
and this rectangle is partitioned into four nonoverlapping rectangle areas $A_{11}, A_{12}, A_{21}, A_{22}$,
and in each of these areas A_{ij} a number z_{ij} is represented which equals $x_i \cdot y_j$, where $x = x_1 + x_2$, and $y = y_1 + y_2$,
then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' an arithmetic representation of a solution z with $z = x \cdot y$ of the multiplication problem (x, y) is included.

Local Properties

In this section a number of properties are identified that characterise the reasoning in a more local manner: each property characterises one reasoning step. For the sake of simplicity, for the example reasoning process persistence of representations in reasoning states over time is assumed, so that persistence does not need to be formulated within each of the properties.

LP1 (arithmetic-geometric)

at any point in time t
if in the reasoning state in trace γ at t an arithmetic representation of a multiplication problem for numbers x and $y < 100$ is present,
then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' a geometric representation of a rectangle ABCD with $|AB| = x$ and $|AD| = y$ is included.

This dynamic property expresses that in reasoning trace γ , if an arithmetically represented multiplication problem occurs, this eventually is translated into a geometric representation. The formalisation of this property in TTL is as follows.

$$\begin{aligned} \forall t \forall x, y < 100 \text{ state}(\gamma, t, \text{arithmetic}) \models \text{multiplication_problem}(x, y) \\ \Rightarrow \exists t' \geq t \exists A, B, C, D \\ \text{state}(\gamma, t', \text{geometric}) \models \text{rectangle}(A, B, C, D) \ \& \ |AB| = x \ \& \ |AD| = y \end{aligned}$$

Further local properties are the following (not in any particular order).

LP2 (arithmetic-arithmetic)

at any point in time t
if in the reasoning state in trace γ at t an arithmetic representation of a multiplication problem for numbers x and $y < 100$ is present,
then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' an arithmetic representation of a splitting of the numbers x and y in 'tens' and digits occurs, i.e., $x = x_1 + x_2$, $y = y_1 + y_2$ with x_1, y_1 multiples of 10 and $x_2, y_2 < 10$.

LP3 (arithmetic-arithmetic)

at any point in time t
if the reasoning state in trace γ at t contains an arithmetic representation of a multiplication problem for (x, y) , with x, y multiple of 10 or less than 10,
then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' an arithmetic representation of a solution z with $z = x \cdot y$ for this multiplication problem for (x, y) is included.

LP4 (arithmetic-arithmetic)

at any point in time t
if in the reasoning state in trace γ at t an arithmetic representation of an addition problem for a finite list z_1, \dots, z_n of numbers of up to 4 digits is included,
then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' a solution $z = \sum_{1 \leq i \leq n} z_i$ of the addition problem is included.

LP5 (arithmetic-geometric)

at any point in time t
if in the reasoning state in trace γ at t an arithmetic representation of a splitting of the numbers x and y occurs, i.e., $x = x_1 + x_2$, $y = y_1 + y_2$,
then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' a geometric representation of a rectangle ABCD with $|AB| = x$ and $|AD| = y$ is included with points P on AB and Q on AD such that $|AP| = x_1$, $|PB| = x_2$, $|AQ| = y_1$, and $|QD| = y_2$.

LP6 (geometric-geometric)

at any point in time t
 if in the reasoning state in trace γ at t a geometric representation of a rectangle ABCD is included with points P on AB and Q on AD,
 then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' the rectangle ABCD is partitioned into four areas $A_{11}, A_{12}, A_{21}, A_{22}$ by two lines $PP'//AD$ and $QQ'//AB$ with P' on CD and Q' on BC.

LP7 (geometric-geometric)

at any point in time t
 if in the reasoning state in trace γ at t a geometric representation of a rectangle ABCD is included that is partitioned into a number of nonoverlapping areas A_1, \dots, A_n ,
 then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' it is asserted that the area of ABCD is the combination of the areas A_1, \dots, A_n .

LP8 (geometric-arithmetic)

at any point in time t
 if in the reasoning state in trace γ at t a geometric representation of a rectangle ABCD with $|AB| = x$ and $|AD| = y$ is included with points P on AB and Q on AD such that $|AP| = x_1$, $|PB| = x_2$, $|AQ| = y_1$, and $|QD| = y_2$,
 and this rectangle is partitioned into four areas $A_{11}, A_{12}, A_{21}, A_{22}$ by two lines $PP'//AD$ and $QQ'//AB$ with P' on CD and Q' on BC,
 then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' arithmetic representations of multiplication problems for (x_1, y_1) , (x_1, y_2) , (x_2, y_1) , and (x_2, y_2) are included.

LP9 (geometric&arithmetic-geometric)

at any point in time t
 if in the reasoning state in trace γ at t a geometric representation of a rectangle ABCD is included with points P on AB and Q on AD,
 and this rectangle is partitioned into four areas $A_{11}, A_{12}, A_{21}, A_{22}$ by two lines $PP'//AD$ and $QQ'//AB$ with P' on CD and Q' on BC,
 and arithmetic representations of solutions $z_{11}, z_{12}, z_{21}, z_{22}$ for the multiplication problems for $(|AP|, |AQ|)$, $(|AP|, |QD|)$, $(|PB|, |AQ|)$, and $(|PB|, |QD|)$ are included,
 then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' within the geometric representation in each area A_{ij} , the number z_{ij} is represented.

LP10 (geometric-arithmetic)

at any point in time t
 if in the reasoning state in trace γ at t a geometric representation of a rectangle ABCD is included which is partitioned into a number of areas A_1, \dots, A_n ,
 and within each of these areas A_i a number z_i is represented,
 then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' an arithmetic representation of an addition problem for z_1, \dots, z_n is included.

LP11 (geometric& arithmetic-arithmetic)

at any point in time t
 if in the reasoning state in trace γ at t a geometric representation of a rectangle ABCD is included with $|AB| = x$ and $|AD| = y$ that is partitioned into a number of nonoverlapping areas A_1, \dots, A_n ,
 and within each of these areas A_i the number z_i is represented,
 and an arithmetic representation of a solution z of the addition problem for z_1, \dots, z_n is included,
 then a time point $t' \geq t$ exists such that in the reasoning state in γ at t' an arithmetic representation of a solution z with $z = x \cdot y$ of the multiplication problem (x, y) is included.

Relationships Between the Dynamic Properties

A number of logical relationships have been established between the properties above. First of all, the three milestone properties together imply the global property:

$$MP1 \ \& \ MP2 \ \& \ MP3 \Rightarrow GP1 \quad (0)$$

Next, each of these milestone properties is implied by a number of local properties:

$$LP1 \ \& \ LP2 \ \& \ LP5 \ \& \ LP6 \Rightarrow MP1 \quad (1)$$

$$LP3 \ \& \ LP8 \ \& \ LP9 \Rightarrow MP2 \quad (2)$$

$$LP4 \ \& \ LP7 \ \& \ LP10 \ \& \ LP11 \Rightarrow MP3 \quad (3)$$

These logical relationships, which can be depicted as an AND-tree, are helpful in the analysis of errors within a given reasoning trace. First it can be checked whether GP1 holds. If this global property does not hold, the three properties MP1, MP2, MP3 can be checked. Given the logical relationship (0), at least one of them will be found not to hold. This pinpoints the cause of the error in part of the process, say MP3. Next, (only) the local properties relating to MP3 are checked, i.e., LP4, LP7, LP10, LP11. Again, due to (3) one of them will be found not to hold. This localises the error.

The Dynamic Analysis Method

The analysis method for the dynamics of reasoning processes as presented here is summarised as follows.

1. Identify the different dimensions or *components* of reasoning states.
2. Determine the different *types of transitions*.
3. Identify relevant *dynamic properties* for the reasoning
 - a. for the process as a whole (global properties)
 - b. for milestones within the process
 - c. for reasoning steps (local properties)
4. Determine logical *relationships* between the different dynamic properties, in an AND-tree form; e.g.,
 - a. local properties imply a milestone property, and
 - b. milestone properties imply a global property.
5. For a given reasoning trace, *check* which of the dynamic properties hold and which do not hold. This can take the form of a diagnosis following the tree structure of the relationships between the dynamic properties. A software environment is available to support this checking process.

The dynamic properties identified can be of different types. Some may be assumed to hold for all proper reasoning traces, others may be used to distinguish different types of reasoning traces or reasoners.

Discussion

The analysis method for the dynamics of reasoning processes put forward and illustrated in this paper was validated on the basis of reports from experiments with 8-9 year old children in classrooms in the Netherlands (Dekker et al., 1982); a similar report has been made by Hutton

(1977). This paper shows how an analysis of these dynamics can be made using traces consisting of sequences of reasoning states over time to describe reasoning processes. It is shown for the example reasoning pattern, how characterising dynamic properties can be identified.

The language used to express dynamic allows for precise specification of these dynamic properties, covering both qualitative and quantitative aspects of states and their temporal relations. Moreover, software tools have been developed to (1) support specification of dynamic properties, and (2) automatically check specified dynamic properties against example traces to find out whether the properties hold for the traces. This provides a useful supporting software environment to evaluate empirical data on the dynamics of reasoning processes.

The same analytic method and software tools can also be applied to reasoning traces produced by software simulation models. This applicability supports the comparison of human reasoning with simulated reasoning.

Further experiments will be conducted, in which also a focus is on the control of the reasoning. For example, at what point in time a translation to a geometric representation is made, and why at that point in time? In the analysis the notion of reasoning strategy will be addressed. Due to the compositional structure of reasoning state a reasoning state can be extended with a component for control information.

Future research will also address the analysis of the dynamics of other types of practical reasoning, both from the syntactical and semantical stream, or their combination; e.g., (Johnson-Laird, 1983; Yang and Johnson-Laird, 1999; Yang and Bringsjord, 2001); see also (Stenning and Lambalgen, 2001). One component of the reasoning state may contain a syntactic formula structure, and another component a mental model or set of mental models. For example, a single component transition can be defined within a syntactic component including A and $A \rightarrow B$, for the derivation of B (and hence adding it to the component) based on the inference rule *modus ponens*. Yet another example, within a semantic component is a transition of a set of mental models, thus providing a formalisation of the dynamics of reasoning based on mental models.

Abstract

Although categorization and multiple-cue judgment are similar tasks, categorization models emphasize *exemplar memory*, while multiple cue judgment routinely is interpreted in terms of mental integration of cue weights that are abstracted in training. We investigate if these conclusions derive from genuine differences in the processes in the two tasks or are accidental to different research methods. The results reveal large individual differences and a shift from exemplar memory to mental cue-abstraction when the criterion is changed from classification to continuous. This suggests that people switch between qualitatively distinct processes in the two tasks.

Introduction

A categorization task typically requires a probe described by a number of binary *features* to be classified into one, of usually two, *categories*. A multiple-cue judgment involves a probe defined by binary or continuous *cues* and typically requires judgment of a continuous *criterion*. Both tasks require inference from known variables to an unknown variable. Despite the structural similarity of the tasks (Figure 1), the most successful cognitive models in the two domains are profoundly different in terms of the computations, cognitive processing, and neural substrate that they imply. Research on categorization often emphasize *exemplar memory* (e.g., Nosofsky & Johansen, 2000): retrieval of memory traces of concrete objects from different categories. In research on multiple-cue judgment, the (explicit or implicit) interpretation is generally that people retrieve abstracted knowledge of cue weights, which is then mentally integrated to perform a judgment (e.g., Einhorn, Kleinmuntz, & Kleinmuntz, 1979).

In this article, we report an investigation into the reasons for these divergent conclusions. From the outset, we can identify two possible answers. The first is that research on multiple-cue judgment has not benefited from the designs and the cognitive modeling needed to disclose the importance of exemplar memory. From this point of view, the conclusions are accidental to different research paradigms and once that we scrutinize the processes carefully we find that they are essentially the

same. A second answer is that the different conclusions derive from the differences that nonetheless distinguish the two tasks; for example, the use of a binary criterion in categorization tasks and a continuous criterion in multiple cue judgment tasks. The latter answer suggests a cognitive system with multiple levels of qualitatively distinct representations that compete to control behavior depending on the requirements (Ashby, Alfonso-Reese, Turken, & Waldron, 1998; Jones, Juslin, Olsson, & Winman, 2000; Juslin, Olsson, & Olsson, 2002).

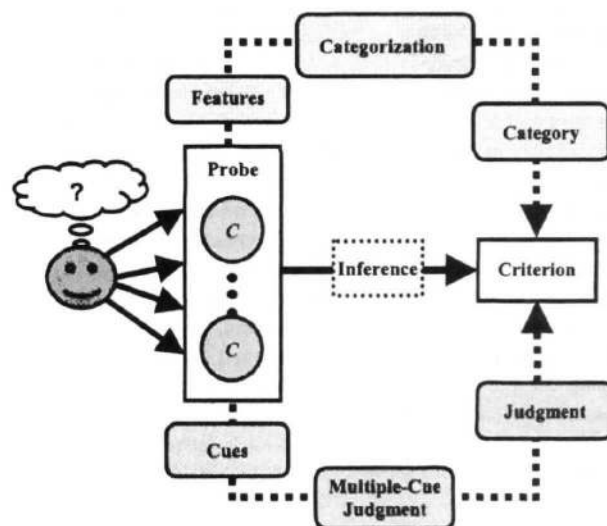

Figure 1: The structural similarity between a categorization task and a multiple-cue judgment task.

The Judgment Task

The task requires participants to use four binary cues to infer a binary or continuous criterion (Jones et al., 2000; Juslin et al., 2002). The judgments involve the toxicity of subspecies of an exotic (but fictitious) Death Bug. The different subspecies vary in concentration of poison from 50 ppm to 60 ppm (a continuous criterion), where concentrations below 55 ppm are harmless but concentrations above 55 ppm are lethal (a binary criterion, harmless vs. dangerous). The toxicity can be in-

ferred from four binary cues of the subspecies (e.g., short or long legs, spots or no spots on the fore-back).

The cues take on values 1 or 0 and the toxicity c of a subspecies is a linear, additive function of the cues:

$$c = 50 + 4 \cdot C_1 + 3 \cdot C_2 + 2 \cdot C_3 + 1 \cdot C_4 \quad (1)$$

C_1 is the most important cue with coefficient 4 (i.e., a relative weight .4), C_2 is the second to most important with coefficient 3, and so forth. The binary criterion b is formed from the continuous criterion by assigning $c < 55$ $b=0$ (harmless), $c > 55$ $b=1$ (dangerous), and $c=55$ randomly as $b=1$ or $b=0$. A subspecies with feature vector (0, 0, 0, 0) thus has poison concentration 50 ppm and is harmless; a subspecies with feature vector (1, 1, 1, 1) has 60 ppm and is dangerous. The continuous and the binary criteria for all the 16 subspecies (i.e., possible cue configurations) are summarized in Table 1.

In training, the participants encounter 11 subspecies and make either *binary judgments* about the toxicity of each subspecies (i.e., "harmless" or "dangerous") or *continuous judgments* about their toxicity (e.g., "The amount of poison is 57 ppm"). As indicated in the two right-most columns of Table 1, five subspecies are omitted in training. (Sets A and B, respectively, denote two different training sets where three omitted subspecies are counter-balanced.) In a test phase, the participants make the same judgments as in the training phase, but for all 16 subspecies and without feedback.

Table 1: Structure of the judgment task. The out-balanced constrained training sets are denoted A and B.

Exemplar #	Cues				Criteria		Set	
	C_1	C_2	C_3	C_4	Cont.	Bin.	A	B
1	1	1	1	1	60	1	E	E
2	1	1	1	0	59	1	T	T
3	1	1	0	1	58	1	T	T
4	1	1	0	0	57	1	O	N
5	1	0	1	1	57	1	N	O
6	1	0	1	0	56	1	N	O
7	1	0	0	1	55	$p=.5$	N	O
8	1	0	0	0	54	0	T	T
9	0	1	1	1	56	1	O	N
10	0	1	1	0	55	$p=.5$	O	N
11	0	1	0	1	54	0	T	T
12	0	1	0	0	53	0	T	T
13	0	0	1	1	53	0	T	T
14	0	0	1	0	52	0	T	T
15	0	0	0	1	51	0	T	T
16	0	0	0	0	50	0	E	E

Note: E = Extrapolation exemplar, T = training exemplar, O = Old comparison exemplar presented in training, matched on the criterion to one of the new exemplars, N = New comparison exemplar presented the first time at test, $p=.5$ assigns binary criterion 1 to the exemplar with probability .5.

A criticism of previous studies that support exemplar models is that often the artificial categories used essen-

tially contain no structure at all. There is thus, in a sense, no other way to solve the task than to memorize the exemplars (Smith & Minda, 2000). Our task is neutral in this respect because it allows perfect performance in training both by exemplar memory and by induction of the task structure (i.e., by inducing Eq. 1).

Cognitive Models

The *cue-abstraction model* assumes that participants abstract explicit cue-criterion relations in training which are mentally integrated at the time of judgment. When presented with a probe the participants retrieve rules connecting cues to the criterion from memory (e.g., "Green back goes with being poisonous"). The rules specify the sign of the contingency and the importance of the cue with a cue weight. For example, after training the rule for cue C_1 may specify that $C_1=1$ goes with a large increase in the toxicity of a subspecies.

With a continuous criterion, cue abstraction suggests that the participants compute an estimate of the continuous criterion c . For each cue, the appropriate rule is retrieved and the estimate of c is adjusted according to the cue weight ω_i ($i=1 \dots 4$). The final estimate \hat{c}_R of c is a linear additive function of the cue values C_i ,

$$\hat{c}_R = k + \sum_{i=1}^4 \omega_i \cdot C_i \quad (2)$$

where $k = 50 + .5(10 - \sum \omega_i)$. If $\omega_1=4$, $\omega_2=3$, $\omega_3=2$, and $\omega_4=1$, Eq's 1 and 2 are identical and the model produces perfect judgments. The intercept k constrains the function relating judgments to criteria to be regressive around the midpoint (55) of the interval [50, 60] specified by the task instructions¹. This formulation essentially provides a cognitive interpretation of the linear additive model known to provide a good account of multiple-cue judgment data (Brehmer, 1994). Predictions by the cue-abstraction model in a continuous task are illustrated in Figure 2A.

The binary judgment involves classification of subspecies into two categories based on their continuous criterion. One way to obtain such judgments from Eq. 2 is by assigning all subspecies with $\hat{c}_R < .5$ as harmless and all subspecies with $\hat{c}_R > .5$ as dangerous. Whenever the estimates are correct ($\hat{c}_R = c$) this implies a relation between classification proportions $p_R(b=1)$ and the

¹ The constrained formulation captures the regression effect within the interval [50, 60] that is introduced by a random error in the cue weights or the process of cue abstraction. For example, for the extreme subspecies, (0, 0, 0, 0: $c=50$) and (1, 1, 1, 1: $c=60$), random error may produce judgments that deviate from 50 and 60, respectively. However, for exemplar (0, 0, 0, 0: $c=50$) we expect the errors to more often produce a judgment above than below 50. For exemplar (1, 1, 1, 1: $c=60$) we expect the errors to more often produce a judgment that is below than above 60. Second: it holds to a good approximation in the data reported below. Third, it provides a four-parameter implementation that is more easily compared to the four-parameter exemplar model described below in terms of the number of free parameters.

criterion c that is a step function. Taking into account that the process is likely to involve error in cue abstraction and decision making, we allow for a sigmoid function in the form of a logistic function (see Figure 1A):

$$p_R(b=1) = \frac{e^{k + \sum W_i C_i}}{1 + e^{k + \sum W_i C_i}} \quad (3)$$

where W_i are the cue weights in a logistic regression and $k = -.5 \sum W_i$. The intercept k implies a crossover from binary judgment 0 to 1 at toxicity 55, as implied by the instructions. When the cue-abstraction model is fitted to binary judgments below, we rely on Eq. 3.

Exemplar models suggest that the participants make judgments by retrieving similar exemplars (subspecies) from long-term memory. The *context model* of perceptual classification (Medin & Schaffer, 1978) suggests that the probability $p_E(b=1)$ of categorization as dangerous equals the ratio between the summed similarity of the judgment probe to the dangerous exemplars and the summed similarity to all exemplars:

$$p_E(b=1) = \frac{\sum_{j=1}^J S(p, x_j) \cdot b_j}{\sum_{j=1}^J S(p, x_j)} \quad (4)$$

where p is the probe to be judged, x_j is stored exemplar j ($j=1 \dots J$), $S(p, x_j)$ is the similarity between the probe p and exemplar x_j , and b_j is the binary criterion stored with exemplar j ($b_j=1$ for dangerous, $b_j=0$ for harmless). J depends on the size of training set of exemplars.

The similarity between probe p and exemplar x_j is computed by the multiplicative similarity rule of the context model (Medin & Schaffer, 1978):

$$S(p, x_j) = \prod_{i=1}^4 d_i \quad (5)$$

where d_i is an index that takes value 1 if the cue values on cue dimension i coincide (i.e., both are 0 or both are 1), and s_i if they deviate (i.e., one is 0, the other is 1). s_i are four parameters in the interval [0, 1] that capture the impact of deviating cues (features) on the overall perceived similarity $S(p, x_j)$. s_i close to 1 implies that a deviating feature on this cue dimension has no impact and is considered irrelevant. s_i close to 0 means that the overall similarity $S(p, x_j)$ is close to 0 if this feature is deviating, assigning crucial importance to the feature. The parameters s_i capture the similarity relations between stimuli and the attention paid to each cue dimension, where a lower s_i signifies higher attention.

The context model was developed for classification. To generate predictions also for judgments of a continuous criterion we relax the model by allowing the outcome index b_j to be a continuous value. The estimate \hat{c}_E of c is then a weighted average of the criteria c_j stored for the exemplars, with similarity $S(p, x_j)$ as the weights (see e.g., DeLoosh, Bussemeyer, & McDaniel, 1997; Juslin & Persson, 2000; Smith & Zarate, 1992).

Predictions

The predictions are summarized in Figures 2 (binary criterion) and 3 (continuous criterion). In both tasks, the models produce similar predictions when all exemplars are presented both at training and test (the upper panels). Both models thus provide accurate representations of the environment, albeit by different means. Figures 3A and 3B illustrate that the good fit of a linear additive model need not be informative in regard to whether cues are really mentally integrated according to a linear model: predictions by an exemplar model are identical. When the extreme exemplars ($c=50$ & 60) and three intermediate exemplars ($c=55, 56, \& 57$) are withheld in training, the models produce distinct predictions.

As illustrated in the lower panels of Figures 2 and 3, the cue abstraction model allows accurate extrapolation beyond the distribution of criteria in the training set [51, 59]. Whenever the correct signs of the cue weights are identified, the most extreme judgments are made for exemplars 1 ($c=60$) and 16 ($c=50$). The exemplar model that computes a weighted average of the criteria observed in training can never produce a judgment outside the observed range (DeLoosh et al., 1997). The most extreme judgments are made for criteria $c=51$ and 59.

With the cue abstraction model there should be no systematic difference between judgments for the "New" and "Old" exemplars with $c=55, 56$, and 57: the process is essentially the same in both cases. However, with the exemplar model there is more accurate judgments for Old exemplars: these judgments benefit from retrieval of identical exemplars with the correct criterion.

One way to predict the relative importance of mental cue abstraction and exemplar memory in the binary and the continuous tasks is by computational considerations (see Juslin et al., 2002). For judgments of a continuous variable—assuming a linear additive model, as people tend to (e.g., Brehmer, 1994)—observation of five exemplars with their criteria is, in principle, sufficient to identify the structure of the task. This system of five linear equations has the unique solution provided by Eq. 1. Given a psychological bias towards linear additive models, the task thus has a well-defined rule-based solution that can be induced from a small number of observations. Binary judgment affords no unique solution, even if the correct function form is assumed and all 16 exemplars are considered. Given the difficulty of inducing a rule-based solution, the participants may have little alternative but to rely on exemplar memory (see Smith & Minda, 2000, for similar arguments).

Note the alternative hypothesis suggested by a *single-systems account* (Nosofsky & Johansen, 2000): that the participants rely on exemplar memory in both tasks. On computational grounds there seems to be no reason why exemplar memory should not be equally applied in both tasks. Both tasks allow a linear combination of criteria stored with exemplars. The hypothesis proposed here is based on a *dual-process account*. Because rule-based knowledge affords better communication and system-

atic elaboration, we expect explicit rule-based processes to be applied when the task structure and the feedback allow participants to induce the task structure, whereas exemplar memory provides a general and flexible back-up system when the task structure or feedback is poor.

Figure 2: Predictions for the binary task. Panel A: Cue abstraction models with no noise and noise for the complete training set. Panel D: Exemplar model with similarity parameter $s=.1$ for the constrained set.

Figure 3: Predictions for the continuous task. Panel A: Cue abstraction models with no noise and noise for the complete training set. Panel B: Exemplar model with all similarity parameter s equal to .0001 and .1 for the complete set. Panel C: Cue abstraction model with noise for the constrained set. Panel D: Exemplar model with similarity parameter $s=.1$ for the constrained set.

Method

Participants

Sixty-four persons participated in the experiment (35 women and 29 men, with an average age of 23.5 years). All participants were undergraduate students at Umeå University and rewarded with 70 SEK (app. 7 US \$) for their participation in the experiment.

Materials and Procedure

The written instructions informed the participants that there were different subspecies of a Death bug. The subspecies differed in toxicity between 50 and 60 ppm, toxicity below 55 is harmless and toxicity above 55 is dangerous. In the binary task condition, the instruction asked the participants to categorize the subspecies into dangerous and harmless. The training phase provided trial-by-trial outcome feedback about the binary criterion ("This bug is dangerous"). In the continuous task condition, the task was to directly estimate the toxicity of the subspecies as a number between 50 and 60. In training, the participants received feedback about the continuous criterion ("This bug has toxicity 57 ppm"). The question on the computer screen was "Is this subspecies harmless or dangerous? (binary task)" or "What is the toxicity of this subspecies? (continuous task)".

The subspecies varied in terms of four binary cues; leg length (short or long), nose length (short or long), spots or no spots on the fore back, and two patterns on the buttock. The cues had the weights 4, 3, 2, and 1 (Eq. 1). The weights determine the portion of toxicity that each cues adds to the total amount. In the analogue stimulus condition, the participants were presented with pictures of the subspecies, in the propositional stimulus condition they were presented with four propositions that provided information about the cue values.

The training phase consisted of 220 trials, where the 11 training exemplars in Table 1 were presented 20 times each. The remaining five exemplars were omitted in the training phase. Two different training sets were used (Sets A and B in Table 1). In Set A, Exemplars 5, 6, and 7 were omitted; in Set B, Exemplars 4, 9, and 10. The exemplars in the two training sets were pair-wise equal in toxicity and the omission of these exemplars was thus counterbalanced across the training sets.

In the test phase, all participants judged all 16 exemplars, twice with an analogue stimulus format and twice with a propositional stimulus format. The stimulus formats were presented in two 2x16 blocks, the order of which was counterbalanced across the participants. No feedback was provided in the test phase. Half of the participants were trained with analogue stimuli and the other half with propositional stimuli, whereas all participants were tested with both presentation formats.

Results

Results and model fits were collapsed over the analogue and propositional conditions, as the aim of this paper is to investigate the relative importance of mental cue abstraction and exemplar memory in binary and continuous tasks. Figure 4 presents model fits (r^2 & Root Means Square Deviation) and mean judgments.

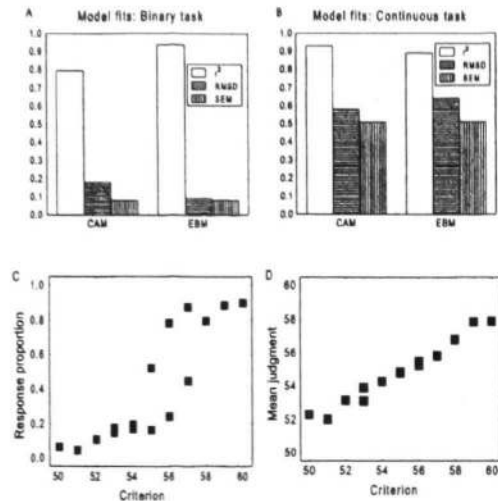

Figure 4: Panel A: Model fits for the binary task. Panel B: Model fits for the continuous task. Panel C: Response proportions in the binary task. Panel D: Mean judgments in the continuous task.

Inspection of Figure 4C suggests exemplar effects in the binary judgment task (notice the difference between new and old exemplars with criterion 55, 56, and 57). The mean difference in proportion of dangerous decisions between old and new intermediate exemplars was $-.33$ (95% CI: $-.45 - .21$). Both the cue abstraction model and the exemplar model were fitted to data. The four parameters in each model were estimated with a Quasi-Newton procedure that minimized the sum of squared deviations between data and model predictions for the last 110 trials in the *training block*. These parameters were used to predict data in the *test phase* (i.e., all free parameters were determined by training data and thus produce cross-validation for training exemplars and genuine predictions for new exemplars).

The exemplar model is clearly superior in the binary judgment task. The model fit indexes in Figure 4A for the binary task, $RMSD$ and r^2 , suggests predominant use of exemplar processes with model fits almost identical to the mean standard error in data (SEM) and r^2 above .90. In the continuous task, the model fits are more ambiguous, although there is a slight advantage for the cue abstraction model (Figure 4B). However, there are nonetheless signs of exemplar effects (e.g., the judgments for the extreme exemplars are at the level of, or below, the judgments for the second-to-most extreme).

A comparison between the two tasks revealed that the percentage of participants showing exemplar effects dropped from 81% in the binary task to 63% in the continuous task ($p = .06$).

Figure 5: Exemplar effect in the data for continuous judgments with the same training and test stimuli. Panel A: Mean difference (slope) with 95% CI between each successive data point. Panel B: Mean absolute difference from the correct value for each data point.

The signs of exemplar effects are evident in Figure 5 presenting data for continuous judgments with the same training and test stimuli. Panel 5A plots the difference between each successive data point (slope) in a graph like Figure 4D. This slope is 1 for perfect judgments. Panel 5A also provides the slope of the best fitting linear regression of the mean judgments on the criterion. Panel 5B presents the mean absolute error of judgment for each criterion. It is clear that the slopes turn negative for the extreme criteria (inability to extrapolate) with more error in the judgments for new exemplars. There is poorer ability to extrapolate the continuous judgments when training and test stimuli were in the same format ($F(1, 30) = 4.62, p = .04$), thus suggesting more exemplar retrieval.

The ambiguous results for the continuous judgments suggest that the group-level data may actually be a mix of the two processes. Investigation of individual participants indeed revealed individual differences. Some participants relied on cue-abstraction, others on exemplar retrieval (Figure 6). Somewhat arbitrarily, but as bench-mark, we deemed best-fitting models accounting for more than 70% of the variance in individual data as producing acceptable fit. On this criterion, 11 participants (34%) were best accounted for by the exemplar model, 13 (41%) were best accounted for by the cue abstraction model, whereas 8 (25%) were not accounted for ($r^2 < .7$ for both models). In sum: although there are exemplar effects also with a continuous criterion, there

is an increased prevalence of cue abstraction with some participants clearly relying on cue abstraction.

Figure 6: Individual-participant data: Panel A exemplifies a participant guided by exemplar retrieval and panel B a participant guided by cue abstraction.

Discussion

The question addressed in this article is why the theoretical conclusions from categorization and multiple cue judgment research are different, considering that the task structure is so similar (Figure 1). Perhaps, the most salient difference between the paradigms is that categorization often involves a binary whereas multiple-cue judgment often involves a continuous criterion.

The results suggest that the differential emphasis in the conclusions is not accidental to different research traditions, with more cognitive modeling in categorization research and more statistical modeling in multiple cue judgment research. Changing the criterion from binary to continuous thus creates a shift from exemplar memory to a mix of exemplar- and rule-based processing that involves cue abstraction in training and cue-integration at the time of judgment. In the continuous judgment condition just as many individual participants extrapolated appropriately and relied on cue abstraction as on exemplar memory. Figure 6 highlights the individual differences in preferred representational mode (see Shanks & Darby, 1998, for similar results). These results raise the question of the appropriateness of the routine procedure of applying quantitative models to group-level data. The exemplar retrieval with continuous judgments moreover seems to increase when training and test conditions coincide.

There is no reason why exemplar memory should not be used in both tasks (as it indeed was by some participants). Exemplar retrieval is an equally efficient way to solve both tasks. However, it seems that as soon as the feedback is informative enough, people eagerly induce explicit rule-based representations, corresponding to the "rule-bias" suggested by Ashby et al. (1998). This suggests that people change between qualitatively distinct representation levels depending on the task properties (Ashby et al., 1998; Jones et al., 2000; Juslin et al., 2002). Jones et al. showed that people spontaneously tend to integrate cues in a task like the one used here, either explicitly by cue abstraction or implicitly by exemplar retrieval. A principled understanding of the

interplay between – and properties of – these distinct levels of representation in human judgment and categorization should be a prime goal of cognitive science.

Abstract

Natural language comprehension involves processing a multitude of words that vary along many dimensions, some of which may reflect statistical regularities in language. These variables may differ in their relative importance across various types of words and tasks. This study used a multiple regression approach to investigate potentially important predictors of noun-verb processing across naming, grammatical categorization, and sentence completion tasks. Although there were some indications of different predictors for nouns vs verb processing, the strongest predictors of response latencies were primarily determined by the types of processing most important for a given task. One variable of particular interest was the newly created Noun-Verb Distributional Difference (NVDD) metric developed by Chiarello et al. (1999). NVDD values reflect statistical regularities in language regarding the typicality of the contexts in which nouns and verbs tend to occur. The results suggest that although noun-verb typicality, as assessed via the NVDD, is a valid measure of regularities in noun-verb contexts within a linguistic corpus, individuals may not be very sensitive to this dimension in standard psycholinguistic processing tasks.

Introduction

Single word recognition is a central component of language processing. The typical approach has been to use a naming or lexical decision (LD) task and a factorial design to investigate the processing effect of one or more variables such as familiarity or imageability while holding other potentially confounding variables constant. In addition, most single word recognition research has tended to use words of different parts of speech without considering grammatical class (e.g., nouns vs. verbs), or has focused on concrete, imageable nouns. Natural language comprehension, however, involves processing a multitude of words varying along many dimensions. These dimensions may be relatively more or less important for various word types, and their relative importance is likely to vary across different forms of language processing (e.g., word pronunciation vs grammatical identification vs sentence integration).

With a few exceptions (e.g., Balota & Chumbley, 1984; Balota, Cortese, & Pilotti, 1999), there have been few attempts to investigate the relative importance of various orthographic and semantic dimensions for responding to

words across tasks using multiple regression procedures. This approach provides the opportunity to study many variables simultaneously, to determine which lexical dimensions account for the greatest amount of variance in reaction time (RT) and accuracy for a particular task, and to assess whether the variance accounted for is unique, or is shared by other variables.

Such a regression approach was used in the present study to investigate the relative importance of different lexical dimensions across three language tasks. To our knowledge no prior regression study has examined whether various predictor variables are equally applicable to words of different grammatical class. This is an important issue because neuropsychological research has shown that nouns and verbs appear to be processed differently in the brain (e.g., Daniele et al., 1994; Koenig & Lehmann, 1996; Sereno, 1999). It is unclear whether these differences are due to neurally separate noun and verb processing systems, or whether these processing differences are mainly due to different semantic dimensions that covary with word class. Investigating several potentially relevant dimensions using a regression approach may be informative regarding these processing differences between nouns and verbs.

One possible reason word recognition research has generally been limited to concrete, imageable nouns, is the lack of word norming corpora available for other word types. A recent study by Chiarello, Shears, and Lund (1999), however, provides imageability ratings, frequency values from the Usenet text corpus of the Lund and Burgess (1996) Hyperspace Analog to Language (HAL) model, and a new measure of noun-verb distributional typicality (the Noun-Verb Distributional Difference, NVDD, metric), for a set of 1197 words: 555 "pure" nouns, 427 "pure" verbs, and 215 words "balanced" for noun-verb usage, as classified by the Francis and Kucera (FK, 1982) norms.

Noun-Verb Distributional Typicality

The new measure of noun-verb usage developed by Chiarello et al. (1999) uses context vectors from the Lund and Burgess (1996) HAL model, where words occurring in similar phrasal and sentential contexts are nearby in high dimensional context space. Context distances were computed between each word and each of the 555 "pure" nouns (according to Francis & Kucera, 1982) and averaged to get a mean noun context distance score. Mean verb distance scores were similarly obtained by computing and

averaging the context distances between each word and the 427 "pure" verbs (Francis & Kucera, 1982). The mean verb context distance was then subtracted from the mean noun context distance, for each word, resulting in a measure referred to as NVDD (Noun-Verb Distributional Difference), indicating the extent to which the word occurs in contexts that are more typical of nouns or verbs. Chiarello et al. (1999) validated the NVDD measure by demonstrating their strong correlation with Francis & Kucera (1982) estimates of noun-verb usage, as well as by examining actual part of speech occurrences for a subset of words in sentence contexts from the Usenet corpus.

The NVDD measure is purely computational, however, reflecting statistical regularities of noun-verb usage in the language corpus. Given the many compelling demonstrations of how information about statistical regularities in a learner's environment can be extracted to result in the learning of various language phenomena (e.g., Elman, 2001; Saffran, 2001a,b), it was of interest to determine whether the NVDD is psychologically relevant for language processing. We therefore examined whether individuals would demonstrate a sensitivity to the contextual typicality of nouns and verbs in their performance on psycholinguistic tasks. The present paper further investigates the psychological validity of NVDD across three different linguistic tasks, whose findings can be compared with our previous lexical decision results.

Prior Lexical Decision Results

Kacirik, Shears, and Chiarello (2000) reported regression results investigating the influence of imageability (ease with which a word arouses a mental image), word length, experiential familiarity, NVDD, and 2 measures of frequency (FK, 1982, and Usenet corpus) on noun and verb lexical decision (LD) response times (RTs).

The results indicated that noun-verb typicality (NVDD) accounted for a significant portion of verb RT on its own, but it did not account for any unique variance with the other variables in the model. For nouns, the opposite occurred, such that NVDD did account for a small, but significant portion of unique variance. These LD results only partially support the psychological relevance of the recently developed NVDD metric, because it was not a very important predictor. LD, however, requires discriminating words from nonwords, and as nouns and verbs are both words, noun-verb typicality may not really be a relevant dimension for making this discrimination. Experiments 2 and 3 of the current study investigated grammatical categorization and sentence completion tasks, both of which should involve language processes for which noun-verb typicality could be more relevant.

The LD results also showed different variables to be more or less important for predicting noun vs. verb RT. Specifically, imageability appeared to be a more important predictor for verb responses, whereas frequency appeared to be more important for nouns. Most importantly, however, the results indicated that although frequency, imageability,

and NVDD could each account for a portion of the RT variance individually, they failed to account for much unique variance.

The biggest predictor of RT was familiarity, individually accounting for 50% or 60% of the variance, for nouns and verbs, respectively. Moreover, when contributions of the other variables were partialled out, around half of the RT variance accounted for by familiarity appeared to be unique (33% for nouns and 30% for verbs). Familiarity's importance in predicting LD RTs is not surprising (e.g., Balota et al., 1999; Gernsbacher, 1984), suggesting that familiarity is probably the most important dimension for discriminating between words and nonwords. More surprising, however, was that about half of the variance accounted for by familiarity was unique.

To continue examining predictors of noun-verb processing, and the psychological relevance of the NVDD metric across various linguistic processes, Experiment 1 examined word naming, Experiment 2 involved noun-verb decision, and Experiment 3 investigated sentence completion.

Experiment 1

This experiment investigated which variables would be the most important predictors for noun and verb naming latencies. Word naming entails activating phonological representations to produce a vocal pronunciation response, and is not thought to require much semantic processing (Balota et al., 1999). This is in contrast to lexical decision, as well as the grammatical categorization and sentence completion tasks examined in Experiments 2 and 3, which mainly involve activating semantics to make a decision and subsequent key press response. Familiarity, frequency, and length were expected to be most influential because of their likely importance in the initial recognition processes involved in activating phonological representations (Balota et al., 1999). In addition, because nouns and verbs primarily differ in meaning and grammatical class, we did not expect differences for the relative importance of predictor variables in this pronunciation task.

Method

Mean latencies from Spieler and Balota's (1997) young adult naming corpus were obtained for 251 nouns and 131 verbs found in our database of 1197 words. Spieler and Balota report that these mean RTs were obtained from 31 Washington University undergraduates (mean age = 22.6), who named a total of 2870 monosyllabic words.

The word length, NVDD, FK and Usenet frequencies, imageability, and familiarity values for each of these words were taken from the Chiarello et al. (1999) database. These 6 predictor variables were combined with the Spieler and Balota naming latencies as the dependent variable.

Results and Discussion

The multiple regression results for noun and verb naming latencies are shown in Table 1. When all 6 variables were in

Table 1: Noun and verb regression analyses for the naming task, Experiment 1.

NOUNS	<u>Sole Predictor</u> <u>Variance</u>	<u>Unique Variance</u> <u>(semi-partial r^2)</u>	<u>Beta</u>	<u>t value</u>	<u>t-test sig. of β</u> <u>p<</u>
NVDD	.00	.00	-.00	-0.08	ns
Image	.01	.00	-.01	-0.11	ns
Length	.11	.12	.35	6.08	.0001

Length	.07	.05	.23	2.52	.05
FK Freq	.02	.00	.04	0.33	ns
Usenet Freq	.03	.00	-.10	-0.73	ns
Fam	.05	.03	-.25	-2.02	.05

Note: $R^2 = .21$, $F(6, 245) = 10.57$, $p < .0001$, for nouns, and $R^2 = .12$, $F(6, 121) = 2.87$, $p < .05$, for verbs

the regression, they significantly accounted for 21% of the RT variance for nouns, and only 12% of variance for verbs. It thus appears that the lexical dimensions typically thought to influence word naming are relatively more important for nouns than verbs. Further examination of the results, however, suggests that although both frequency measures appear to be additionally influential for nouns, they do not account for any unique variance. The variance they account for appears to be subsumed by length and familiarity. Indeed, the main conclusion from these results is that similar dimensions (length and familiarity) were most important predictors for both noun and verb RTs. These findings are in contrast to the previous LD results where, after familiarity, there was some indication that different predictors were important for noun vs verb processing. This suggests that noun-verb processing differences are due to semantics and/or result from postlexical processing.

NVDD was not found to be a significant predictor for noun latencies, and was only marginally significant for verbs, accounting for 2% unique variance. Thus, both the LD and naming results provide minimal support that individuals are sensitive to regularities in the contexts in which nouns and verbs occur. Another possibility is that neither of these tasks involves explicitly activating word class information. Perhaps a task that does require explicit activation of noun or verb meaning and/or grammatical class information, will show greater effects of noun-verb typicality.

Experiment 2

This experiment investigated the relevance of the typicality of contexts in which nouns and verbs tend to occur (NVDD) for deciding whether a word is a noun or verb. In contrast to LD and naming, this task requires the explicit activation of

grammatical class information in order to make the noun-verb decision.

Method

Participants

Forty native English speaking University of California, Riverside undergraduates (20 males) participated in the experiment in exchange for course credit or pay (\$6.00).

Stimuli

The same set of 152 nouns and 137 verbs, varying in NVDD, from Kacirik et al. (2000) were employed here.

Procedure

Each trial began with the presentation of a 400 ms fixation point, followed by 100 ms blank screen, which was followed by presentation of the target word. Participants were required to decide whether each item was a noun or a verb by making a button press response as quickly as possible. Targets remained on the screen until they responded, and the inter-trial interval was 1500 ms. Participants were told that nouns were words naming a quality, person, place, or thing, while verbs are words that express an action or the occurrence of an event, and given some examples of each. Fifteen practice trials preceded the experiment.

Results and Discussion

The noun and verb multiple regression analyses are presented in Table 2. When all the variables were included in the regression model, it was better at predicting noun-verb decision than naming latency, such that 44% of the RT

Table 2: Noun and verb regression analyses for the noun-verb decision task, Experiment 2.

NOUNS	Sole Predictor Variance	Unique Variance (semi-partial r^2)	Beta	t value	t-test sig. of β $p <$
NVDD	.04	.03	.19	2.87	.005
Image	.37	.28	-.57	-8.50	.0001
Length	.02	.01	.12	1.82	ns

Fam	.18	.03	-.20	-2.40	.05

Note: $R^2 = .44$, $F(6, 144) = 18.57$, $p < .0001$, for nouns, and $R^2 = .40$, $F(6, 123) = 14.39$, $p < .0001$, for verbs

variance for nouns, and 40% of the RT variance for verbs, was accounted for.

For nouns, imageability followed by NVDD was the most significant predictor of noun-verb decision times. Although familiarity individually accounted for 5% of the noun RT variance, it was not found to contribute a significant amount of unique variance. Imageability and NVDD were also the most important predictors of unique variance for verbs. Familiarity was also a strong predictor of verb latency on its own, but in contrast to the noun results, it also accounted for a small significant unique amount of variance.

Imageability therefore appears to be the most influential dimension for deciding whether a word is a noun or a verb. Furthermore, much of imageability's contribution and the variance it accounts for seems to be unique. There is also some indication that imageability is more important for nouns than verbs in the noun-verb decision task. This is contrary to the LD results, where imageability appeared somewhat more important for verbs. A possible explanation for these results is that since nouns are generally more imageable than verbs, a highly imageable concrete word encountered in the context of the noun-verb decision task must be a noun and could be responded to very rapidly (Chiarello et al., 1999). A negative correlation should thus be expected between imageability and decision latencies for verbs, because low imageability words are more likely to be verbs (Chiarello et al., 1999), and should be responded to quickly. The obtained correlation, however, was positive, suggesting that imageability does not facilitate the noun-verb decision per se. Instead, we suggest it facilitates earlier processes such as the speed of word meaning activation, enabling subsequent noun-verb decisions to be made more rapidly.

As expected, noun-verb typicality (NVDD) was significantly correlated with both noun and verb decision

latencies ($r = .21$, $p < .01$, and $r = -.32$, $p < .0001$, respectively). Given that noun-verb decision does explicitly involve processing part of speech information, it is surprising that NVDD was not more important and only accounted for 3% and 7% unique variance for nouns and verbs, respectively. Recall, however, that the NVDD is a measure of the typicality of contexts in which nouns and verbs occur. All tasks investigated thus far involved single word processing, and may not reflect the influence of the fundamentally contextual nature of the NVDD metric. It is possible that NVDD may be most relevant for processing words in sentence contexts.

Experiment 3

This experiment investigated whether noun-verb contextual typicality would influence response speed for deciding whether a word could be sensibly integrated into an incomplete sentence. If sentence context is assumed to constrain possible completions, faster latencies would be expected for words that are highly typical nouns or verbs than for words less typical of their grammatical class.

Method

Participants

Forty native English speaking University of California, Riverside undergraduates (20 males) participated in the experiment in exchange for course credit or pay (\$6.00).

Stimuli

Incomplete sentence frames, which could be sensibly completed by either a high or low NVDD noun or verb, were created. For example, *punish* and *smack* are high and low NVDD verb completions for "the father wanted to

his son", respectively, and *tavern* and *pub* are high and low typicality noun completions for "They walked into the _____". We created such incomplete sentences for 80 verbs (40 high and 40 low) and 88 nouns (44 high and low) from the set of 152 nouns and 137 verbs used by Kacirik et al. (2000). Sentences were normed and balanced for sensibility and cloze probability. Nonsensical completions were created by re-pairing sentence frames and target words (e.g., *She had to punish the text*).

Procedure

Each trial began with the presentation of a 500 ms fixation point, immediately followed by the appearance of the incomplete sentence. After 1200 ms, the target word appeared above the sentence, allowing participants enough time to read the sentence prior to the target's appearance. Both the sentence and target word remained on the screen until they responded. Participants had to decide whether the target word was a sensible completion to the sentence and responded by pressing a key as quickly and accurately as possible. The inter-trial interval was 1000 ms. Twenty-four practice trials were completed prior to the experiment.

Results and Discussion

Table 3 presents results from regression analyses for the related condition (i.e., when the noun or verb was a good completion to the sentence). Contrary to our predictions, noun-verb contextual typicality (NVDD) was not found to be relevant for sentence integration, a task where it was expected to strongly influence processing. Indeed, it is surprising that with the exception of Usenet frequency for nouns ($r = -.22$, $p < .01$) and imageability for verbs ($r = -.25$, $p < .01$), none of the variables were significantly correlated with decision latencies. Noun RT did not correlate with NVDD ($r = -.18$, *ns*), imageability ($r = -.20$, *ns*), length ($r =$

$.07$, *ns*), FK freq ($r = -.12$, *ns*), and familiarity ($r = -.11$, *ns*). Verb RT was also not correlated with NVDD ($r = -.16$, *ns*), length ($r = .09$, *ns*), FK freq ($r = -.01$, *ns*), Usenet freq ($r = -.10$, *ns*), and familiarity ($r = -.11$, *ns*). These results suggest that lexical-semantic dimensions identified as being important for single word recognition are much less relevant for integrating words into sentences. Indeed, when all the variables are in the regression model, they only account for a marginally significant (13%) portion of variance for nouns, and a non-significant 12% of the variance for verbs.

One possible explanation is that these are lexical variables, representing characteristics of single words, and this task is primarily measuring sentence integration. The nature of the sentence, therefore, is also an important source of variance for this task. Indeed, it may even be the most important, suggesting that perhaps "sentence-level variables" such as sentence length, imageability, or meaningfulness, would be better predictors of decision latency. Another possibility is that these lexical variables are still important for initial word recognition and meaning activation, but that their influence dissipates once a word has been recognized, such that they are not involved in higher-level sentence integration processes. This would predict these lexical dimensions, and possibly NVDD, to significantly contribute to initial word recognition processes that happen in on-line sentence comprehension.

General Discussion

The relative influence of variables on processing nouns and verbs in naming, noun-verb decision, and sentence completion tasks was investigated. There were some indications in our previous lexical decision results that, after familiarity, different dimensions might vary in terms of their relative importance for noun versus verb processing.

Table 3: Noun-verb regression analyses for the sentence completion task, Experiment 3.

NOUNS	Sole Predictor Variance	Unique Variance (semi-partial r^2)	Beta	t value	t-test sig. of β p<
NVDD	.03	.03	-.18	-1.57	ns
Image	.04	.05	-.25	-2.24	.05
Length	.00	.00	.01	-0.08	ns
FK Freq	.01	.00	.03	0.18	ns
Usenet Freq	.05	.04	-.28	-1.85	.10
Fam	.01	.01	.11	0.81	ns
VERBS	Sole Predictor Variance	Unique Variance (semi-partial r^2)	Beta	t value	t-test sig. of β p<
NVDD	.03	.03	-.17	-1.45	ns
Image	.06	.05	-.25	-2.12	.05
Length	.01	.00	.01	0.10	ns
FK Freq	.00	.01	.19	1.04	ns
Usenet Freq	.01	.01	-.20	-1.02	ns
Fam	.04	.00	-.05	-0.38	ns

Note: $R^2 = .13$, $F(6, 81) = 1.96$, $p < .10$, for nouns, and $R^2 = .12$, $F(6, 73) = 1.66$, *ns*, for verbs

Although the present study also found some evidence that different variables were relatively more important for the processing of nouns vs verbs across tasks, these differences were fairly subtle. They generally involved differences in the strengths of relationships between variables and RT, or in the unique amount of variance accounted for by each variable. Thus, the main conclusion from this study should be that the strongest predictors of RT do not depend on word class *per se*, but are determined primarily by the type of processing necessary for a given task. Specifically, word length and familiarity were most important for naming both nouns and verbs, familiarity is the most important dimension for discriminating words and nonwords (regardless of whether the item is a noun or verb), imageability and noun-verb typicality were most relevant for deciding whether a word is a noun or verb, and imageability was the most relevant lexical variable for integrating words into sentences.

A variable of particular interest in the current study was the typicality of contexts in which nouns and verbs tend to occur, as measured by Chiarello et al.'s (1999) recent NVDD metric. Despite the fact NVDD captures statistical regularities of noun-verb usage based on the typicality of contexts in which they tend to occur (Chiarello et al., 1999), it does not seem very relevant for the processing of nouns and verbs across a variety of tasks. Some results did find noun-verb typicality to correlate with lexical and noun-verb decision latencies. In these cases, however, part of that correlation with RT was also accounted for by other variables, such that the unique portions of variance accounted for by NVDD were rather small. This was true even in tasks where noun-verb typicality was expected to influence processing.

There is no doubt that individuals are sensitive to some statistical regularities present in the language environment, many of which can affect processing (e.g., Saffran, 2001a). The present findings suggest, however, that this may not be true for all such regularities. The typicality of contexts in which nouns and verbs tend to occur, as measured via NVDD, appears to be a valid regularity within a linguistic corpus. Yet individuals may not be very sensitive to this dimension in standard psycholinguistic tasks.

Abstract

This research adapts theories of graph comprehension to investigate the factors affecting how easily a graph can be described. We find that the structure of a graph—the number of *visual chunks* (visually distinct units of information) to be described—influences the communicative quality of elicited descriptions. The work extends our understanding of graph comprehension by investigating the relationship between comprehension and description processes. This research occurs in the context of understanding how to design graphical description tasks for the Test of Spoken English.

Introduction

Graphs are a ubiquitous communication tool. Instructors describe graphs to communicate concepts, perhaps requiring students to uncover a graph's main point. A doctor might describe a graph to a patient to make a point about treatment ("see how your cholesterol level has been decreasing since you began the new diet?"). Yet we know little about the cognitive processes engaged when people describe a graph. Research on graph description can contribute to our understanding of how people integrate visual and verbal information in the performance of everyday tasks. From a practical standpoint, such research can provide guidelines for designing graphs that facilitate description.

Instead, much of the research on graphs has focused on graph comprehension—how we encode and interpret elements of a graph to draw out key pieces of information (Carpenter & Shah, 1998; Lohse, 1993; Pinker, 1990), typically in response to relatively narrow tasks (e.g., "Who had a greater market share in 1983?"). The few studies that investigate spontaneous descriptions of graphs have focused on what is described (e.g., global trends vs. local, piecemeal descriptions [Carswell, 1993; Carswell et al., 1998]; trends vs. comparisons [Zacks & Tversky, 1999]) and the organization of the descriptions (Shah, Hegarty, & Mayer, 1999; see below) rather than on the *communicative quality* of the description. One reason for this oversight might be the lack of a rigorous measure of communicative quality.

In the work presented herein, we apply a theory of graph comprehension to predict the characteristics of graphs that facilitate descriptive communication. To measure the quality of descriptions produced by alternative graphs, we use a theoretically grounded and empirically validated measure of communicative quality: the scoring rubric from the Test of Spoken English (TSE®).

The next section provides some background on the TSE, its scoring rubric, and the real-world problem that motivated this research.

The Test of Spoken English

The real-world problem

The goal of the Test of Spoken English (TSE) is to measure a test-taker's communicative competence in Northern American English. It is taken by approximately 30,000 non-U.S. citizens each year, who are seeking to be teaching assistants or healthcare professionals in the U.S. The test consists of 12 questions that elicit a range of communication functions (e.g., describe, compare, state opinion) through a variety of visual and verbal prompts. The questions are presented visually in a booklet and aurally by a taped interviewer; test-takers' spoken responses are recorded. Responses are scored by trained raters employing a well-defined scoring rubric (see below).

One question (illustrated in Figure 1) prompts for a description of a statistical graph. Test-takers are given one minute to respond. The task mirrors the type of communication using graphs done by teaching assistants and healthcare professionals. None of the other 11 questions presents a data graph.

The graph below shows what people of two age groups value about their work. Describe the information given in the graph.

WHAT PEOPLE VALUE ABOUT WORK

Figure 1: Illustrative graph question [Fewer visual chunks].

This type of graph-description question occasionally poses problems for TSE scoring. According to the raters, certain graphs elicit speech that displays a lower ability in

English than would be expected based on responses to all other test questions. However, many graphs evidenced no such difficulties. Analyses of data from the past two years of TSE administrations confirm that graph description questions are more likely than questions with non-graph prompts to elicit such discrepant performance (Katz, Xi, Kim, & Cheng, 2002).

The issue of what characteristics of a graph lead to descriptions that communicate better is critical to the TSE. If a graph is hard to describe, it might give an unfair advantage to test-takers with better graph-reading skills (i.e., a more sophisticated "graph schema"; Pinker, 1990), who can make sense of poorly constructed graphs. A test-taker's ability to read and interpret graphs should not influence their score on a graph question. Indeed, the accuracy of a person's response to a graph item is not considered in the score, only the degree to which the person evidences certain competencies associated with spoken English.

The challenge is to create graphs that contain enough information so as not to trivialize the description (which would eliminate any differences between test-takers) yet are straightforward to describe, allowing test-takers to show off their communicative skill without other factors getting in the way. Ultimately we seek to develop guidelines for the development of graph questions that validly measure communicative competence.

TSE Scoring Rubric

Responses to TSE prompts are scored according to the published "TSE SCORE BAND DESCRIPTOR CHART" (TOEFL, 2001). This scoring rubric defines four key communicative competencies: discourse, functional, sociolinguistic, and linguistic competence. The chart also specifies the types of response characteristics for these competencies at each of the five possible score levels (20, 30, 40, 50, and 60). Although these several competencies are considered during scoring, each response receives a single, holistic score representing the raters' judgment of which score band level was best evidenced in the response. The score band chart and associated training materials were developed based on research into the components of communicative competence (Douglas & Smith, 1997; Powers, Schedl, Wilson-Leung, & Butler, 1999).

Two communicative competencies are particularly relevant to the issue of graph comprehension: discourse competence and functional competence.

Discourse competence relates to the coherence and cohesiveness of a response. Is the response well organized and well developed, and does the speaker cue the listener to the organization (e.g., "First we see that...", "In contrast...")? For the graph in Figure 1, a partial response demonstrating low discourse competence is: (ellipses refer to short pauses in speech)

- the good hours...ah for age...ah...between age ...50*
 (1) *and 60 is ten percent....And...the pleasant*
...colleagues...for...ah...for age...20 to 30...is ten
percent...and...ah for...50 to 60 is twenty percent....

Responses low in discourse competence tend to be list-like, consisting of phrases connected by "and" but showing neither a strong organizing structure nor development. A response showing stronger discourse competence is:

- ...for adults...uh...between age two,...20 to 30,...they*
value interesting work as their most important
 (2) *thing....well...for the old man...that's not*
important....Other points I should compare is uh...is
the low stress ...for the old man they...they prefer low
stress and...while for the younger men...

This response guides the listener better by using phrases such as "for the old man..." and "Other points I should compare..."

Functional competence is the ability to use language to transfer information and ideas to accomplish a goal. It is demonstrated by the extent to which a person communicates an intended goal. For example, we all know people who "beat around the bush" while you are wondering when they will get to their point. For the graph in Figure 1, a partial response demonstrating low functional competence is:

- Ok, people...around the age...20 to 30...I guess*
started like...ah...just youngsters...they are...um...
 (3) *they good hours up like twenty percent ...and...*
only...ah...at the age of 20 to 30 ...the people who
are interested ...are only forty percent

This response does not communicate what information was provided in the graph, partially because the speaker misrepresents the meaning of "good hours" and "interesting work." Response (1), in contrast, does a good job of describing the information and so was rated higher on functional competence than was response (3).

The other two competencies appear less likely to be affected by the particular characteristics of a graph. **Sociolinguistic competence** is the ability to demonstrate an awareness of audience and situation. **Linguistic competence** refers to more basic speech issues such as vocabulary selection, pronunciation, and syntax.

The Theory

Most theories of graph comprehension include the processes of (a) encoding a visual feature of the graph or data (sometimes referred to as a "visual chunk") and (b) interpreting that feature with respect to basic graph knowledge (e.g., a line going up means something is increasing) and specific graph content (e.g., "bicycle sales are increasing"). Carpenter and Shah (1998) provide evidence that comprehension occurs through repeated cycles of encoding and interpretation, building up more inclusive understanding of the graph. Thus, the more information (the greater the number of visual chunks) in a graph to integrate, the longer it takes to comprehend a graph.

We hypothesize that fewer visual chunks similarly lead to higher quality descriptions. Fewer pieces of information to describe leaves more time and cognitive resources for

communicative tasks such as providing cues for the listener as to the organization of the description, describing each piece of information succinctly, and so forth.

What are the visual chunks in multi-variable bar graphs? Shah, Hegarty, and Mayer (1999) argue that each group of bars associated with a particular value on the x-axis form a visual chunk. Consistent with this theory, participants' descriptions of bars graph tend to be organized around these chunks. However, this impoverished definition depends solely on the x-axis scale of the graph, accounting neither for the visual properties of the data nor what information is represented by each group of bars. The present work requires a richer definition of visual chunks.

Our theoretical claim is that a visual chunk should play the same role as a proposition in text comprehension models (e.g., Kintsch, 1998). That is, in addition to being visually distinct as guided by Gestalt principles, a visual chunk must encode a single unit of information. A group of bars need not be a single visual chunk as is claimed by Shah et al. Rather, that group would be encoded as a single unit only if it represented a single unit of information (e.g., "Older people value salary the most").

Consider the graphs shown in Figures 1 and 2. These graphs represent the same data set, but switch the variables represented along the x and z (bar shades) dimensions. Which should be easier to describe? Figure 1 incorporates fewer visual chunks than does Figure 2 (two vs. five), so according to our hypothesis should elicit descriptions with higher communicative quality. Figure 1 has two groups of bars, each with one category that is much higher than the rest: describing this feature succinctly summarizes the data represented in the group. Thus, a straightforward description would be to make the global comparison within one age group (e.g., "For Age 20-30, interesting work is the most important") and then the other age group. While such a response does not necessarily capture every nuance of the data, it does capture the essential difference between the two groups. By our enriched definition of visual chunks, it is important that each x-axis group of bars in Figure 1 contain an obviously maximal value. Otherwise, each group might be perceived as separate chunks (each bar), potentially diminishing the quality of descriptions that the graph elicits.

Figure 2: Alternative form of Figure 1
[More visual chunks]

Figure 2, in contrast, has five visual chunks: the relative height of the bars within each category. Thus, more time is needed to comprehend the graph, and the communicative quality of any descriptions of this graph should be lower than those of Figure 1.

This task analysis is not necessarily intuitively obvious. Although there are fewer visual chunks in Figure 1, the graph introduces five different shade-category mappings that might need to be either remembered or refreshed by looking at the legend (Lohse, 1993). From this alternative task analysis, Figure 1 might impose a heavier working-memory (WM) burden than Figure 2 because the latter has only two shades representing the two age groups. This alternative task analysis predicts that Figure 2 would elicit descriptions of superior communicative quality.

To test the visual chunk hypothesis, we conducted an experiment that manipulated two factors with the potential to affect the descriptive ease of a graph. First, as illustrated by Figures 1 and 2, we created two graph organizations for each of four data sets by switching the variables represented along the x-axis and by the differently shaded bars (the z-variable). One graph organization presents a smaller number of visual chunks (2-3 chunks depending on the data set) than the other organization (4-6 chunks). These two graph organizations will be referred to as the **few-chunks** (e.g., Figure 1) and **many-chunks** (e.g., Figure 2) graphs. The few-chunks graphs' organization minimizes the amount of information to be described, and is therefore predicted to elicit better descriptions.

An alternative to the visual chunks hypothesis is that a comparison between two groups is simply a more natural way to describe a graph. In other words, any superiority of the few-chunks graphs might be due to a particular descriptive strategy.

This alternative hypothesis suggests the possibility of drawing participants' attention to the fewer chunks even within a many-chunks graph (e.g., seeing the maximal values for the two age groups in the many-chunks graph). To investigate this possibility, we introduced alternative task prompts. **Open-ended** prompts were the same for all graphs and asked the participant to "Describe the information given in the graph." **Directive** prompts identified the critical contrast in the graph, suggesting more directly what should be described. For example, for Figure 1 the prompt was "Describe the changes in work values between the two age groups."

Method

Participants

Thirty-nine students (19 female, 18 male) participated in the experiment. Ten students¹ were recruited from each of four universities in the U.S., and students participated at their local institution. Eighty-five percent of participants were

¹ Due to technical difficulties, one participants' data were lost, so one school contributed only nine students.

doing graduate or post-graduate work; others were juniors or seniors. Participants ranged in age from 21 to 45, with an average age of 29. Students' reported fields of study were medicine (20%), math or science (18%), humanities (12%), business (8%), and social science (7%).

Each institution was asked to recruit eight non-native English speakers and two native English speakers. Most of the participants ($n = 19$) were native speakers of a Chinese dialect; other languages were reported by no more than two or three participants (a mix of Asian, European, and Middle Eastern languages). There were seven native English participants because one institution recruited only one native English speaker instead of the requested two. Most of the students had been living in the U.S. for fewer than two years ($n=22$); the remaining students were evenly split between those that had lived in the U.S. 10 or more years ($n=9$) and between 2 and 10 years ($n=8$).

Materials

We constructed four data sets to be graphed as bar charts. Each data set had its own story line, which had been reviewed by professional test developers for comprehensibility to non-native speakers of English. The data represented the interaction of two independent variables, with one variable having fewer levels (2-3) than the other (3-5). The variables with fewer levels were either years or age groups (as in Figure 1). The other variables were either nominal categories (e.g., work values) or intervals (e.g., hours in a day).

We created two graphs from each data set, for a total of eight graphs. One graph in a pair placed the 2-3 level variable along the x-axis and represented the other variable on the z dimension (the different shades of bars)—this organization created the few-chunks graphs. As per our enriched definition of visual chunks, on the few-chunks graphs, each group of bars included one bar (unique to that group) clearly higher than the others. The many-chunks graph was created by switching the variables represented along the x and z dimensions.

Design

The independent variables of graph organization and prompt directness were implemented in a completely within-subjects design: each participant received all four graph types. The organization type alternated, with half the subjects receiving few-chunks graphs first and half receiving many-chunks graphs first. Because of the possibility of one prompt type influencing the next, that variable was implemented using an ABBA design, with half the subjects receiving an open-ended prompt first and half receiving a directive prompt first.

Preliminary analyses suggested no *a priori* differences among the participants from each school in terms of their communicative competence in English or in their familiarity with reading graphs.

Procedure

Each university conducted one data collection session of 10 students. Sessions were typically conducted in a language lab or similar equipped facility. Besides a test booklet, each student had a tape recorder and headphones. Students heard the prompts over their headphones and spoke their responses, which were recorded on audiotape.

The questions were administered in two sets, with a short break between the sets; each set consisted of nine non-graph questions followed by two of the experimental questions. After both sets were administered, students were given a brief graph familiarity questionnaire. The questionnaire consisted of several questions concerning graph interpretation, a section on self-reported graph familiarity, and a short demographic questionnaire.

Measures

We obtained three types of dependent measures from each response: response latency, holistic scores, and four component scores. **Response latency** is the number of seconds between the end of the spoken prompt and when the participant began speaking. The timing was done by a research assistant unaware of the purpose of the experiment, using an on-line stopwatch while listening to each tape.

Each response was also scored by highly experienced TSE raters, each rater having participated in many rating sessions each year for five or more years. Raters produced a **holistic score** in a way identical to how actual TSE responses are scored. To provide finer-grain scores than the 5-level scale described earlier, each rater was asked to indicate whether a score fell into the high, middle, or low end of the score band. Thus, raters provided scores such as "high 40" or "low 60." Raters often discuss responses in this way, so producing this additional information was not difficult. In converting these relative rankings into scores, "middle" scores were unadjusted to facilitate comparison between these scores and the typical score scale for the TSE. In the analyses, a "high" score adds 3.3 to the band level (e.g., "high 40" becomes 43.3) whereas a "low" score subtracts 3.3 from the band level ("low 60" becomes 56.7).

Finally, each rater was asked to provide a score for each of the **component competencies** in the TSE Score Band Chart, as described earlier. Thus, each response received a discourse, functional, sociolinguistic, and linguistic score. These scores were rated on the typical 5-level (20-60) scale.

Results

We look at the effects of graph organization and prompt type from three perspectives. First, what are the effects on response latency? According to Carpenter and Shah (1998), a greater number of visual chunks should lead to longer latencies because of the greater number of encode-interpret cycles need for comprehension. Second, what are the effects on holistic scores? As we are looking at within-subject performance, any effects suggest an influence other than a person's own communicative competence on the score (i.e., variance irrelevant to the construct intended to be

measured). Finally, as a follow-up to the effects on score, we look at the effects on the components of the score—the individual scores on discourse, functional, sociolinguistic, and linguistic competence.

We ran a 2x2 repeated-measures MANOVA, with graph organization (few- or many-chunks graphs) and prompt type (directive or open) as within-subjects factors and response latency as the dependent measure. There was a significant main effect of graph organization ($F(1,37^2)=4.0, p=.034$). Participants spent less time inspecting the few-chunks graphs before responding ($M=5.5; SD=3.7$) compared to the many-chunks graphs ($M=6.8; SD=4.6$). The main effect of prompt type was not significant nor was the interaction of graph organization and prompt.

Similar results were obtained for holistic scores. An identical 2x2 repeated-measures MANOVA revealed a significant effect of graph organization ($F(1,38)=8.1, p=.007$). Participants received higher scores when responding to the few-chunks graphs ($M=47.7; SD=9.1$) compared to the many-chunks graphs ($M=46.1; SD=9.5$). The main effect of prompt type was not significant nor was the interaction of graph organization and prompt.

The effects of graph organization on response latency and holistic scores were also observed in the sub-sample of seven native English speakers, albeit attenuated due to ceiling effects. Native speakers were quicker to respond to few-chunks graphs (3.6 sec) than to many-chunks graphs (4.2 sec) and produced better responses to those few-chunks (60.7 versus 59.5). These trends are consistent with the idea that the effects of graph structure are not just due to language skill, but rather that by using non-native speakers we accentuated differences that otherwise might have been difficult to detect.

Table 1. Mean (SD) scores by graph type.

Competence Component	Graph Type	
	Few-chunks	Many-chunks
Discourse	47.1 (8.6)	45.3* (9.9)
Functional	47.1 (8.7)	45.8 (9.9)
Sociolinguistic	46.2 (8.8)	45.5 (9.1)
Linguistic	48.0 (8.8)	47.2 (8.5)

Note. Each graph type score is the mean of the two scores for each participant. $N = 37$ per cell because one participant's component scores were unavailable. $p < .05$

What types of effects does graph organization have on participants' responses? Are responses to few-chunks graphs more expressive or more linguistically precise? While we might expect graph organization to affect how well organized a response is (i.e., discourse competence), it might be the case that a poorly organized graph increases WM load, so impinges on all language competencies.

Table 1 shows the effect of graph organization on each of the competency scores. As expected, discourse scores were significantly higher (via two-tailed, paired-samples t-test) for the few-chunks graphs: responses to these graphs were rated as more coherent and cohesive. There was an almost significant difference on the functional scores, whereby participants' responses to few-chunks graphs reflected language more appropriate to the task than did their responses to many-chunks graphs. There were no differences between the graph types in participants' ability to express their knowledge of audience (sociolinguistic) or in their pronunciation or grammar (linguistic).

Thus far, the results are consistent with the model that better performance is achieved with graphs that have fewer visual chunks. But are participants describing the visual chunks predicted by the theory? For the few-chunks graph in Figure 1, participants' descriptions should include the global comparison between the highest category in a bar group and the other bars in that group (e.g., "Interesting Work is most important for the 20-30 year olds"). For the many-chunks graph, descriptions should instead include discrete comparisons within a category (e.g., "Interesting Work is more important to the 20-30 year olds than to the 50-60 year olds").

To address whether participants describe the expected visual chunks for these two graphs, we analyzed the first piece of information mentioned in their responses. Given the speeded nature of the task, the first graph feature mentioned should be the most salient to the participant.

Participants' descriptions were consistent with their describing the two graphs in terms of the predicted visual chunks (Table 2). Participants mentioned first the global features of the data significantly more often when the graph was organized to accentuate these features (few-chunks graph) and mentioned first the discrete comparisons (the relative-height visual chunks) of the many-chunks graph ($\chi^2(1)=11.8, p<.001$).

Table 2. Graph type by first description.

Graph Type	Global Comparison	Discrete Comparison
Few-chunks (Figure 1)	19	1
Many-chunks (Figure 2)	8	10

² Due to technical difficulty, one participants' latency was not obtained.

Discussion

The research presented in this paper replicates and extends basic research on graph comprehension. The results provide support for the hypothesis that graphs with fewer visual chunks are easier to describe. Participants took less time to scan the few-chunks graphs before speaking, which replicates Shah and Carpenters' (1998) results. Graphs with fewer chunks also elicited descriptions of greater communicative quality. Furthermore, the organization of a graph had a very specific influence on the descriptions provided by participants: graphs with fewer visual chunks led to more cohesive and coherent descriptions. If the many-chunks graphs were worse because of lower overall comprehensibility, we would expect more aspects of descriptive competence to be affected. Future research might further extend Shah and Carpenter's processing model to explain the mechanisms by which the higher quality descriptions are facilitated.

Interestingly, incorporating a directive prompt had no influence on participants' descriptions. Although it is dangerous to draw conclusions from null results, this lack of effect is consistent with the idea that visual chunks are a visual processing phenomenon and might not be influenced by directions on problem-solving strategy.

The visual chunks hypothesis—fewer visual chunks leading to descriptions of higher communicative quality—has practical implications, suggesting desirable characteristics of graph questions for the Test of Spoken English. For example, two or three visual chunks in a graph might be the limit of what is reasonably possible to describe within one minute. For multi-variable bar graphs, this recommendation would mean limiting the number of bar-groups placed along the x-axis and, as per the enriched definition of visual chunks, ensuring that each group encodes a single unit of information.

The visual chunks hypothesis is applicable to a wider range of graph types, as long as we can adequately define the visual chunks. For example, other research (Carpenter & Shah, 1998; Carswell, 1993; Shah, Hegarty, & Mayer, 1999) suggests definitions of visual chunks for multi-function line graphs: each non-parallel line is a visual chunk, although each "reversal" in a line (e.g., changing from an upwards to a downwards slope) is perceived as a separate chunk. By assuring that any line graphs have no more than two or so visual chunks according to these definitions, we would predict such graphs to be straightforward to describe.

In line with the overall theme of the conference, applied research should adapt theories and results from the basic research literature to solve real-world problems, and then contribute back to the theoretical literature from which it drew. By applying theories of graph comprehension to produce empirically supported recommendations for the design of TSE graph questions and, in the process, enriching the theoretical construct of visual chunks, the applied research presented in this paper achieves these goals.

Abstract

Research on knowledge organization and how this develops with education and training may provide insight into the alarmingly limited effectiveness of school HIV education curricula. The present study investigates the nature of adolescent knowledge of HIV and its relationship to reasoning. Middle and high school students were interviewed about their understanding of HIV and were also asked to critically examine problem scenarios that contained myths about HIV. The findings suggest that adolescents lack understanding of basic biological concepts around which they could build well-structured schemata of HIV. As a result, their HIV knowledge exists as a collection of disjointed facts, not conducive to effective application for reasoning. The implications for school-based HIV interventions are discussed.

Introduction

Despite growing awareness about HIV and AIDS, the outbreak of the disease continues unabated. Current assessments of the demographics of AIDS indicate that the disease disproportionately hurts the young, the poor, and urban minorities (CDC, 1999). Schools respond to the problem by producing educational interventions, aimed to teach adolescents about HIV risks and prevention. In particular, the New York City Board of Education mandates its schools to provide six hours of HIV Education annually at every grade level.

Unfortunately, in spite of such educational efforts, the statistics remain grim. Evaluations show that many existing interventions, while succeeding in increasing teenagers' knowledge about HIV and AIDS, do not lead to the decrease in high-risk behaviors (Brown et al., 1992; Langer & Tubman, 1997). These failures lead HIV educators to a conclusion, currently prevalent in HIV education literature, that knowledge about HIV has little bearing on real-life behavior.

We believe that in many previous studies, the relationship between knowledge of HIV and its real-life application was obscured by methodological weaknesses of HIV knowledge assessment measures. Typically, these studies assess knowledge as the ability to answer simple factual questions by selecting from true/false or multiple-choice answer options (Siegel et al., 1995). Such measures do not provide any insight into the nature and organization of adolescents' HIV knowledge which is critical to its applicability. The present study addresses two questions. First, what is the

nature of adolescent knowledge about HIV? Second, to what extent do adolescents apply this knowledge when reasoning and evaluating information in the context of HIV? Answering these questions employing cognitive methods could provide important information for improving HIV Education curricula for American schools.

Research on expertise has long established that differences between expert and non-expert knowledge extend well beyond the difference in content richness. Studies show that some forms of knowledge organization are more suited for effective application than others. Expert knowledge is coherent and is organized in meaningful patterns around key concepts and ideas (Chi et al., 1981). In contrast, novices frequently organize their knowledge schemata around superficial surface attributes, rather than big ideas (Chi et al., 1982). Compared to novices', experts' knowledge schemata also contain more interrelations among individual concepts and ideas (Chi et al., 1981). As a result, experts have more efficient methods of deciding which chunks of information are essential for solving a particular problem, of retrieving that information efficiently and of applying it correctly. While novice and expert knowledge represent two endpoints of the trajectory, the development of expertise is a long process, which may be conceptualized as a gradual shift from flat and fragmentary to systematic and multi-layered knowledge structures (diSessa, 1993). This process is non-monotonic; often, an increase in knowledge results in a temporary drop in performance, while the new knowledge is being integrated with the existing knowledge (Patel & Groen, 1991).

Studies of lay understanding of health and disease provide us with domain-specific information about the kinds of knowledge that lay people use when reasoning about health issues. When reasoning about health, lay adults frequently rely on their intuition, as well as cultural, social and experiential knowledge (Sivaramakrishnan & Patel, 1993). In doing so, they often misattribute disease causality, viewing symptoms or co-factors of diseases as their causes. Lay scientific knowledge of relevant biological concepts is dissociated from experiential and cultural knowledge, fragmented and is often used opportunistically. This results in low internal consistency, self-contradictions, "loose ends", factual errors and misconceptions (Patel, Kaufman, & Arocha, 1999).

Findings from research on expertise and health cognition suggest that in order to assist effective real-life reasoning, adolescent models of HIV need to integrate superficial factual knowledge, conceptual biological knowledge, and experiential/practical knowledge into a coherent, uniform system. However, schools typically teach students about HIV within health education curriculum, which is separated from science/biology curriculum. HIV education is factual in nature. Moreover, while HIV education is usually introduced in early grades, the first comprehensive biology course is taught in high school, with little connection to adolescent real-life health concerns.

We hypothesize that in the prevalence of the current educational practice, integration of different kinds of knowledge and deep understanding of the mechanism of HIV will not occur. Therefore, adolescents are likely to have model of HIV that is incomplete and saturated with misconceptions, based on practical analogies and non-normative intuitive biology (Carey, 1985). In spite of its deficiency, this model is likely to include accurate factual knowledge of HIV risks and prevention factors. As a result, reliance on this model of HIV is likely to enable adolescents to successfully pass multiple-choice survey assessments, but is not likely to help them reason through complex real-life situations that require deeper understanding. We also hypothesize that while older adolescents may have more basic biological knowledge than younger adolescents, their knowledge is likely to be fragmented and not assimilated into coherent conceptual model, essential for effective reasoning and problem solving. As a result, adolescent ability to reason about novel situations in the context of HIV is expected to be limited. If confirmed, our hypotheses have important implications for the structure of knowledge-based HIV interventions.

Method

Subjects

The subjects include twenty adolescents from two New York inner-city schools, including ten seventh-grade middle school students (4 boys and 6 girls) and ten high school students from grades 9 through 12 (5 girls and 5 boys). The subjects are referred to by the school level (MS = middle school; HS = high school).

Procedure

Each subject participated in an individually administered 45-minute session which included two assessment measures, a semi-structured interview about HIV and a reasoning task that required evaluating information on a simulated website about ways to reduce the risk of HIV infection. The purpose of the interview was to assess students' knowledge about HIV

risks and prevention, as well as their understanding of the underlying biological concepts. Questions of the interview were designed to cover the scope of HIV issues without requiring specialized biological knowledge. In the reasoning task, subjects were presented with a simulated web site about HIV, supposedly created by a group of high school students. The site contained four passages that presented and supported three erroneous claims and one accurate claim about ways to reduce the risk of HIV infection. Understanding the erroneous nature of the information in the passages required basic knowledge about HIV infection and disease progression. After reading each passage, students had to express and justify their opinion about the truthfulness of the information. This paper presents analysis of students' performance on one of the erroneous passages which is presented below.

Passage 2

If you had unprotected sex, you can minimize the risk of becoming HIV-positive by expelling the virus from your body through urine and sweat.

As you probably know, HIV is transmitted through bodily fluids: blood, sperm, etc. This means HIV lives in those fluids and travels with them. If one person's infected fluids get inside another person, the second person also becomes infected. Logically, if infection gets inside a body through fluids, it can also get out of the body through fluids. Fluids that leave human body are urine and sweat. So, if your condom broke, making a lot of fluid leave your body can minimize your risk of getting HIV. To lose fluids, drink lots of water (this will make you go to the bathroom a lot); put on warm clothes and do something physically active. The trick is to do these things early, before the virus has a chance to multiply and become strong.

Coding Scheme for Conceptual Understanding

The analysis of students' knowledge draws on cognitive research in science education concerned with characterizing progressions of conceptual understanding (e.g., Vosniadou, 1999) and on research in the development of biomedical understanding (Patel et al, 1995). Based on consultations with HIV educators, pilot testing and students' responses to the interview, three conceptual models of HIV were generated: *advanced*, *intermediate*, and *naïve*. The models reflect students' understanding of three concepts: the nature of HIV, the mechanism of HIV-infection, and disease progression. Students were assigned to a model, if at least two out of these three concepts were consistent with the model description. Two investigators scored a portion of the protocols, to ensure satisfactory level of inter-rater reliability.

Advanced Model involves understanding of HIV-relevant biological structures and processes on the cellular level, without requiring specialized biological knowledge. This understanding should be evident on the following dimensions: 1). Definition of HIV. Students recognize that HIV is a virus with specific cellular-level structural and functional components (e.g., lacks organelles). 2). Mechanism of HIV infection. HIV enters the body through exchange of bodily fluids and penetrates T-cells of the immune system. 3). Disease progression. HIV replicates within T-cells and eventually destroys them and disables the immune system.

Intermediate Model involves understanding of HIV on systemic, but not on the cellular level, as reflected on the following dimensions: 1). Definition of HIV. HIV is a biological entity (details of the viral structure and characteristics are not provided; replication is not mentioned) 2). Mechanism of HIV infection. HIV enters the body through exchange of bodily fluids. Entering T-cells is not mentioned. 3). Disease progression. HIV compromises the immune system, and the body succumbs to opportunistic infections. The role of T-cells may be mentioned, but without any notion of intracellular processes.

Naïve Model does not employ relevant biological concepts on either systemic or cellular level. Instead, it is built around intuitive lay concepts of health and disease. Scientific biological concepts are either not known, or not integrated with HIV knowledge. Students characterized by this model lack basic biological concepts around which they could organize their knowledge of HIV. This model, however, does not preclude individuals who hold it from knowing an extensive collection of facts about HIV risk factors and prevention measures. The naïve model is reflected in the following understanding of the three critical concepts: 1). Definition of HIV. HIV is an illness. No mention is made of the virus as a causal agent. 2). Mechanism of HIV infection. HIV enters the body. Bodily fluids are not implicated in the process. 3). Disease progression. It makes the person sick. No mention is made of the effect of HIV upon the immune system.

Coding Scheme for the Reasoning Task

The method of *semantic representations* was chosen for the analysis of excerpts of protocols of students' reasoning and information evaluation. Semantic network analysis is a formal method for representing relations among concepts through directed, labeled graph structures (Patel & Groen, 1986). In these structures, nodes represent concepts and links (directional arrows) represent relations among them

(see Figures 1 and 2 for examples). The relations are binary relations, such as *causal*, *conditional*, *alternating or* and *exclusive or* relations. Semantic network is a method that allows one to analyze verbal protocols for the direction of reasoning (forward vs. backward), coherence and granularity of concepts.

Results and Discussion

The Results and Discussion section is organized into two parts. The first part, *Conceptual Understanding of HIV*, presents the analysis of students' models of HIV based on their responses to the semi-structured interview. The second part of the results, *Reasoning in the Context of HIV*, presents adolescents' responses to the reasoning task, described in the Methods section.

Conceptual Understanding of HIV

The classification of individual students' HIV models is presented in Table 1. On the basis of the stated criteria, 9 middle (MS) and 2 high school (HS) students' models were classified as naïve, 5 HS students were classified as intermediate and 3 HS were designated as advanced. Numbers in bold represent dimensions consistent with the model assignment for that student.

Table 1: Classification of students' HIV models.

	Naive	Intermed	Advanced
Virus			
Middle	1, 2, 3, 4, 5, 6, 7, 8, 9	10	
High	1, 3, 2, 5	6, 8, 9	4, 7, 10
Infection			
Middle	1, 2, 3, 4, 5, 6, 7, 8, 9, 10		
High	1, 3, 9	2, 5, 6, 8	4, 7, 10
Progress			
Middle	2, 3, 4, 5, 6, 7, 9	1, 8, 10	
High	1, 3, 6	2, 5, 8, 9	4, 7, 10

Understanding at the Naïve-Model Level. The eleven students assigned to this model (MS 1-9, HS1, HS3) showed almost no understanding of the biological concepts of virus, infection, and immune system, crucial for developing a more advanced model of HIV. When asked what a virus was, these students either characterized it as "sickness" (MS1, MS2, MS4, MS9), or provided specific examples (e.g., "stomach virus", "coughing virus") (MS3, MS7, HS1, HS2). Students' characterization of infection was similar to their characterization of virus. Nine students (MS2, MS3, HS1 and HS2) showed no evidence of having a conception of the immune system. Only two students (MS1 and MS8) were able to state that HIV destroyed

T-cells and weakened the immune system (e.g., MS1 described T-cells as "police officers" that help fight diseases).

Not having a basic understanding of infection, these students had no common theme that would unite different routes of HIV transmission (e.g., exchange of fluids). All the children associated HIV with sex. Older children also associated it with drugs (HS2) and exchange of blood (HS1 and HS2), thus illustrating that an increase in HIV knowledge may not correspond with an increase in understanding. Without seeing exchange of fluids as the common theme in all of the routes of transmission, adolescent understanding of how protection measures work remains weak (e.g., Interviewer: "If you use a condom, can you still catch HIV or not?" MS3: "I don't know"). Such lack of understanding of how exactly HIV is transmitted during sexual intercourse may lead students to believe that they can control HIV by regulating the amount of sex that they have. Indeed, two adolescents (MS2 and MS4) mentioned that people who had HIV could make themselves feel better, if they stopped having sex.

Without perceiving a virus as a microorganism, students had to find an alternative causal agent for the disease. Some subjects avoided the challenge by providing no causal agent at all, while two subjects (MS4 and HS2) mentioned dirt. The following example illustrates a 7th-grader's (MS4) misconception about the process of infection, which involves sex and dirt: "See, most people, like, they don't actually wash after having sex. See, if the person is dirty, ..., you know, like the dirt, it goes into skin, like, it stays there for a long time, then it starts to go further in, then it starts mixing with blood, and that's how AIDS could probably form." This misconception makes students vulnerable to the erroneous belief that washing after sex may prevent infection. Additional potential misconceptions result from students' lack of understanding of the process of disease. Not knowing how HIV affects the human body over time, students in this model also typically did not understand the connection between HIV and AIDS. They referred to them as two different diseases, with one being more dangerous than the other (MS1, MS2, MS3, MS7, MS9, HS1, HS2).

Understanding at the Intermediate-Model Level. The six students assigned to this level (MS10, HS2, HS5, HS6, HS8 and HS9) had some biological understanding of HIV at the systemic level. Although none of the students could describe the viral structure or life cycle, four of them realized that HIV was a particle with physical properties, such as shape and size (e.g., HS6: "It might be a cell-looking thing"). Their understanding that the process of HIV infection involved exchange of fluids allowed them to unite various routes of HIV transmission around a single

theme. Five of the students understood that HIV affects the immune system - and thus destroys body's defenses - and defined AIDS as the advanced stage of HIV infection (e.g., HS3: "AIDS is the sickness itself."). Overall, these students had conception of HIV that was sufficiently biologically grounded to provide some framework for organizing facts about HIV. As a consequence, they did not share any of the misconceptions, exhibited by the naïve students.

Understanding at the Advanced Model Level. The three students who demonstrated this level of understanding (HS4, HS7 and HS10) defined HIV as a virus, and described the virus as a microorganism that lacks organelles, but contains genetic material and can replicate inside of a host. They knew that the virus entered human body through exchange of fluids and penetrated white blood cells, replicated inside of these cells and eventually destroyed them. Both students stated that as the number of viral cells increased and the number of white blood cells decreased, the body became unable to fight opportunistic diseases.

Reasoning in the Context of HIV

Reasoning at the Naïve-Model Level. Refuting the erroneous information in reasoning Passage 2 requires understanding that most HIV particles are "anchored" in white blood cells in the blood stream, and therefore, can not be expelled from the body through fluids. Students whose conception of HIV is at the naïve level do not have this understanding: in their model, HIV affects not specific cells that are located in the blood, and (for most, though not all students in this group) not even the blood in general, but "the body." Sweat and urine flow out of "the body", so the scenario should sound convincing to these students. The following justification of the agreement with passage provided by a seventh-grader (MS3) demonstrates the effect of naïve model of HIV on reasoning, "It makes sense... because the stuff is in the body, and you just need a release, release all of it out... before it really catches your body." Semantic network of this student's reasoning is provided in Figure 1. The network illustrates how this student's reasoning, while coherent, involves the level of conceptual granularity that is too crude to expose the fallacy of the myth.

Nine out of eleven naïve-level students (MS 3-9, HS1 and HS2) agreed that HIV can be expelled through urine and sweat. Some of these students (MS 7 and MS 8) initially said that HIV could not be expelled, but later found the explanation in the passage convincing enough to change their mind. One of the students (HS1) gave additional support to his reasoning by providing an experiential analogy to the case of a person defeating cancer, "Yeah, this is true, this is true. Cause people can stop it like that. By exercising, like they said. Like that

lady, like I told you, she exercised her way out of cancer, so I think this is true, you can exercise your way out of HIV probably.” Such opportunistic use of practical knowledge is typical of lay reasoning about health (Sivaramakrishnan & Patel, 1993). Notably, the subject who provided the analogy had explicitly stated in the course of the interview that HIV is incurable (HS1: “Once you get HIV, it’s like, that’s it, there is no coming back to it.”)

ACT: Action, ALT: Alternative, COND: Conditional Relation, EXC: Exclusive, LOC: Location, RSLT: Result, TEM: Temporality

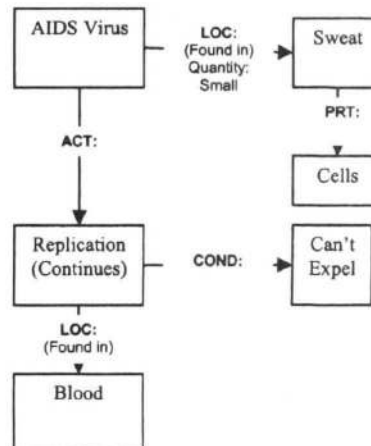

Figure 1: Semantic network of naive-model reasoning.

Two students showed resistance to the myth presented in the passage, in spite of low biological understanding of HIV. One student (MS2) rejected the idea on the basis of common sense/practical reasoning, asserting that had information in the passage been true, HIV would have been defeated by now. However, she also conceded that the information in the passage was “a little-little true cause somebody wrote it.” This illustrates that while common sense may be very useful in everyday health reasoning, its effectiveness is limited, if not supported by biological understanding. Only one naive-level student (MS1) refuted the myth on the basis of biological reasoning, stating that HIV could not be expelled from the body through urine and sweat.

Reasoning at the Intermediate-Model Level. Compared to the students assigned to the naïve model, the adolescents in this group had deeper understanding of the biological basis of HIV. However, the expertise literature characterizes a stage of development in which an increase in knowledge is accompanied by a temporary decrement in performance. Patel and Groen (1991) describe this as the intermediate effect,

characteristic of a period during which recent knowledge is not yet fully assimilated. This phase of temporary disorientation is evident in the reasoning of intermediate level students. For example, unlike naïve model students, most intermediate model students understood the role of bodily fluids in HIV transmission. However, they often failed to utilize this information by inferring that different fluids contained different amounts of virus and did not interact with one another. As a consequence, four out of six students assigned to this model still found the “in with fluids, other with fluids” explanation convincing (e.g., HS6, “A fluid is what makes you get AIDS... drinking gets fluids out of your system... It probably would help.”) Two students (HS2 and HS8) were able to refute the myth, although with some hesitations. Overall, intermediate model level understanding of HIV does not yet provide sufficient conceptual basis for consistent efficient reasoning in the context of HIV.

Reasoning at the Advanced-Model Level. All three students characterized at this level (HS3, HS7, HS10) rejected the myth with very high degree of certainty. This is not surprising, given their relatively rich conceptual model of HIV. In addition to knowing that HIV could enter human body with fluids and travel with them, these students also knew that the virus entered the blood stream, penetrated white blood cells and replicated within them. This allowed them to understand how the majority of the HIV particles were anchored in the bloodstream, thus uncovering the flaw of the passage, e.g., “AIDS virus, it’s found in sweat... but only in minor quantities, so you can’t just expel it, if you do it, there is going to be virus still in your blood that will just keep replicating.”

ACT: Action, ALT: Alternative, COND: Conditional Relation, EXC: Exclusive, LOC: Location, PRT: Part

Figure 2: Semantic network of advanced model reasoning.

Figure 2 provides a semantic network of that student's (HS7) reasoning. The figure illustrates that while the complexity of the reasoning is comparable to that of the naïve model in Figure 1, the explanatory reasoning and use of conceptual knowledge demonstrates a greater degree of understanding.

Conclusions

In this study, students with adequate factual knowledge of HIV risks and prevention often lacked genuine conceptual understanding of HIV. With little conceptual understanding, students had difficulty evaluating dubious claims and reasoning about practical issues in the context of HIV. The dissociation between factual knowledge and conceptual understanding of HIV parallels the dissociation between HIV and science education in the schools. With biology taught separately from factual HIV education and introduced in later grades, adolescents have little understanding of the concepts of virus and immune system, which are critical to building accurate conceptual models of HIV. As a consequence, HIV knowledge remains in the form of a disjointed and sometimes erroneous collection of facts, which have minimal applicability to problem solving. When adolescents enroll in a high school biology course, they receive some grounding in the concepts that are relevant to understanding HIV. However, they do not receive an opportunity to integrate this biological knowledge with factual knowledge and the biological knowledge remains inert.

The present study cautions researchers against making a hasty conclusion about the lack of connection between knowledge of HIV and sexual behavior. We are not implying that understanding of HIV is the only factor that influences sexual risk taking. Non-cognitive factors (e.g., sexual arousal) can exert strong influence on decision-making (Lowenstein, 1996). However, in-depth understanding of basic HIV concepts is crucial to the success of any educational intervention. This study is part of a research program designed to impart robust conceptual understanding of HIV to adolescents.

Acknowledgments

This research is supported by American Educational Research Association postdoctoral fellowship award to the first author. We thank student who participated in this study, the educators who gave us their enthusiastic support and the schools that provided us with research sites. This paper has greatly benefited from critical comments and discussions provided by David Kaufman.

Abstract

We present an analysis of hypothesized advantages of pictorial representations for improving learning and understanding of pre-algebraic quantitative reasoning. We discuss a "Picture Algebra" strategy that has been used successfully by 6th grade students as part of a new middle school mathematics curriculum. This strategy supports students in sense making both as they construct pictorial representations and as they use them to cue appropriate computations. Although we demonstrate that 6th grade students can use this strategy to successfully solve algebra-level problems, our detailed production rule analysis revealed limitations in our instructional approach and targeted areas for improvement.

Introduction

As part of a larger effort to develop a 6th grade mathematics course including both a textbook and Cognitive Tutor software (cf., Koedinger, Anderson, Hadley, & Mark, 1997), we have been exploring the use of pictorial representations to support student reasoning and learning (Rittle-Johnson & Koedinger, 2001). Here we investigate the claim that pictorial representations can help students gain early entry into algebraic reasoning and build a foundation that will facilitate more effective learning of formal algebra.

Why might using pictures or diagrams be advantageous? Cognitive scientists have presented arguments and experiments for the advantages of diagrams (e.g., Cheng, 1999; Larkin & Simon, 1987). According to Larkin and Simon (p. 98), "a diagram can be superior to a verbal description for solving problems" for three reasons. First, diagrams reduce problem-solving search by providing localized groupings of relevant information. Second, diagrams reduce the need for matching symbolic labels. Third, diagrams support perceptual inferences that are often easier than corresponding symbolic inferences.

Others have presented arguments for the use of diagrams for mathematics instruction in particular. The mathematics standards of the National Council of Teachers of Mathematics (NCTM, 2000) recommends

use of pictures to support students in developing a conceptual understanding of mathematics. Pictorial representations are used extensively in Asian curricula (cf., Singapore Ministry, 1999). This usage *may* be a factor in the success of Asian countries on international mathematics assessments (TIMSS, 1996).

Despite these arguments for the advantages of pictures, there is also reason for caution. One argument for the use of alternative representations, like pictures, is that traditional instruction focuses too much on error-prone rote learning. However, students may also acquire rote procedures when learning to use alternative representations. Further, learning an alternative representation takes time that might be better spent learning the standard representation.

In this paper we introduce the "Picture Algebra" strategy, present student data on the use of it, and discuss a production rule model of the strategy and implications for transfer and instructional design.

Picture Algebra

Try to solve the Cans problem shown in Table 1 and reflect on the strategy that you use to do so. We have informally observed that many adults do not directly infer what arithmetic operations are needed to solve this problem. Instead, most begin by translating the problem statement to one or more algebraic equations, for instance, $x + (x + 9) + (x + 17) = 227$. They then perform transformations on the equation to arrive at a solution. Although a few use other means (cf., Hall et al., 1989), most find this problem difficult without the use of algebraic equations. In other words, this is arguably an "algebra problem" that we might expect to be out of reach of students without algebra instruction, for instance, 6th graders.

Figure 1A shows a 6th grade student's solution to this problem using a "Picture Algebra" strategy that was taught to students as part of our middle school mathematics curriculum. Like other problem-solving strategies, Picture Algebra can be described in two phases: a representation phase and a solution phase. In the representation phase, the student first translates the

Table 1. Three Problems Solved by 6th Graders

Cans: The sixth, seventh and eighth grade classes brought in canned goods for the needy. They collected 227 cans between the grades. Sixth grade collected 9 more cans than eighth grade, and seventh grade collected 17 more cans than the 8 th grade. How many cans did each grade collect?
Beanie: Robin has 6 fewer beanie babies than Angie. If they have 42 beanie babies altogether, how many beanie babies does Robin have?
CD: Carissa wants to buy the latest Out o' Sync CD. She also wants to buy a magazine and a poster about her favorite band. The magazine costs \$8 less than CD, and the poster costs \$12 less than CD. The total cost for all three items is \$46. How much does each item cost?

phrase "sixth grade collected 9 more cans than eighth grade" into a box diagram by drawing a box to represent the cans collected by the 8th grade and a larger box to represent the cans collected by the 6th grade. The larger box is made up of two smaller boxes, one that is the same size as the 8th grade box and one that represents the 9 more cans the 6th grade collected. Similarly, the student draws two boxes to represent the 7th grade cans. In both cases, the extra box off to the right is labeled with the given "more-than" values, 9 and 17. In the final step of the representation phase, the student represents the total number of cans, 227, by drawing a bracket to the right of all the boxes.

This picture representation and the algebra equation, $x + (x + 9) + (x + 17) = 227$, are "informationally equivalent" in Larkin & Simon's terms. The three equal sized boxes on the left are analogous to the three x 's in the equation, the extra boxes represent the + 9 and + 17, and the bracket and the 227 represent the equal sign and right hand side of the equation. Despite this similarity, the picture and equation representations are not "computationally equivalent". Whereas the equation is a 1D "horizontal" representation, the picture is 2D and takes advantage of both the horizontal and vertical dimensions to better support the inferences needed to solve the problem.

As we step through the Picture Algebra solution phase, notice how inferences are visually supported in a way they are not in the analogous equation solving steps. The first step in the solution phase is to parse or comprehend the representation, picture or equation. Past research has shown that both equation comprehension (Payne & Squibb, 1990) and equation production (Heffernan & Koedinger, 1998) are particularly difficult sets of skills for students to acquire. For instance, students must learn when they can and cannot rearrange elements of an equation. Although experts know they can in effect ignore the parentheses in " $x + (x + 9) + (x + 17)$ " and transform the expression into " $x + x + x + 9 + 17$ " and then " $3x + 26$ ", the steps involved are non-obvious to students and prone to error. In contrast, the analogous steps in the

Picture Algebra strategy are visually supported. The vertical organization of the bars makes it more apparent that the three equal unknown boxes can be grouped separately from the two extra boxes for 9 and 17. As a consequence, students can "see" that if they subtract these extra boxes, they will be left with the three equal boxes. Notice the arithmetic on the left in Figure 1A where the student computes both $9 + 17 = 26$ and $227 - 26 = 201$. This step is analogous to the "subtract from both sides" transformation in equation solving, however, it is more perceptually intuitive as students can visualize chopping off the extra boxes. Next the student divides 201 by 3 (see the bottom middle of Figure 1A) to get the value, 67, of the three equal boxes. Finally, the student adds back the 9 and 17 to get the values of cans collected by the 6th and 7th grade.

Student Solution Data

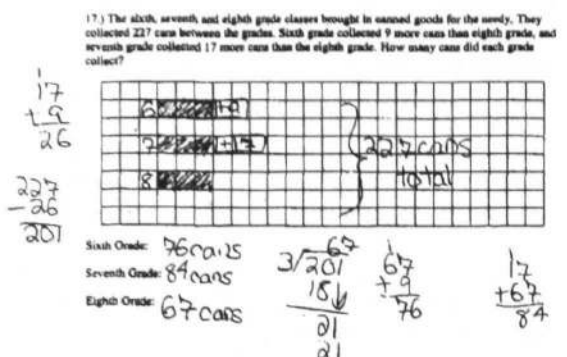

We analyzed 35 sixth graders' solutions to the three problems shown Table 1. The Cans and Beanie problems were given as part of a unit test. To get a sense for whether the representation or solution phase of Picture Algebra is more difficult for students, we provided a correct picture representation for some students but not for others. Half the students were given a test in which a diagram was given for the Cans problem but not for the Beanie problem. The remaining students were given a test in which a diagram was given for the Beanie problem, but not the Cans problem. Students solved the CD problem (with no diagram provided) as part of a warm-up activity on a later day. (One student was absent on each day.)

The Cans problem involves three unknown quantities (cans collected by 6th, 7th, and 8th grades) and more-than relations between these quantities. Students were initially instructed on Picture Algebra with simpler two quantity more-than problems. The Beanie problem also has two quantities but is more difficult because of the less-than (or "fewer") relation between them (Lewis, 1989). The CD problem combines both dimensions of difficulty as it involves three quantities and less-than relations. One question of interest is whether these dimensions of difficulty are independent.

Overall Performance Results

The first result of note is that 6th graders can effectively use pictorial representations to solve "algebraic" problems. They were 68% correct on both the Cans and Beanie problems and 32% correct on the CD problem. Such problems are challenging for many older students. For instance, Bednarz & Janvier (1996, p. 120) found that pre-algebra students (same age as US 7th graders) were only 5% correct on the following problem:

380 students are registered in sports activities for the season. Basketball has 76 more students than skating and swimming has 114 more than basketball. How many

2.) Carleen wants to buy the latest Out o' Style CD. She also wants to buy a magazine and a poster about her favorite band. The magazine costs \$8 less than the CD, and the poster costs \$12 less than the CD. The total cost for all three items is \$46. How much does each item cost?

(B) Correct size-preserving picture for CD problem

2.) Carleen wants to buy the latest Out o' Style CD. She also wants to buy a magazine and a poster about her favorite band. The magazine costs \$8 less than the CD, and the poster costs \$12 less than the CD. The total cost for all three items is \$46. How much does each item cost? M = \$20, C = \$28, P = \$24

(C) Wrong picture for CD problem

2.) Carleen wants to buy the latest Out o' Style CD. She also wants to buy a magazine and a poster about her favorite band. The magazine costs \$8 less than the CD, and the poster costs \$12 less than the CD. The total cost for all three items is \$46. How much does each item cost?

(D) correct abstract picture for CD problem

Figure 1. Correct and incorrect 6th grade students' Picture Algebra solutions.

students are there in each of the activities?
As another reference point, Koedinger & Alibali (1999) collected data on college students' performance on the following relatively simple problem:

There are 38 students in class. If there are 6 more girls than boys, how many boys are in the class?
Students in a college algebra course were only 54% correct and even CMU students with a mean math SAT of 719 were 86% correct.

Students given a picture on the Cans and Beanie problems were 71% correct in both cases and were 65% correct on both without the picture. That being given the picture did not help much on these problems indicates that the representation phase was relatively easy for students. In contrast, the representation phase on the CD problem was not easy. Students drew a good picture in only 32% of CD solutions, but were 64% correct when they did. They were only 17% correct when a picture was missing or incorrect.

We were surprised at students relatively poor performance on the CD problem (32%) given that two key sources of difficulty in that problem, 3 quantities and less-than relations, were each present individually in either the Cans problem (3 quantities) or the Beanie problem (less-than relation). A simple surface-level analysis of problem difficulty factors would predict that students would be, at worst, 42% correct (.65*.65) on the CD problem. Clearly, such a surface level analysis is insufficient to understand why the CD problem was so hard for students. Our production rule analysis below provides a better explanation.

Diagramming Strategies

We classified the pictures students drew into 5 categories: size-preserving, incomplete, wrong, abstract, and no-diagram. In a "size-preserving" picture, all quantities, or parts of quantities, are represented by boxes whose sizes correspond with the

relative sizes of the quantities. That is, bigger quantities are represented by bigger boxes. Unknown quantities can be any size, but equal quantities must be represented by equal size boxes. All quantities are represented and all known quantities or parts of quantities are labeled with their given value. Figures 1A-B show examples of "size-preserving" pictures. An "incomplete" picture was one that was otherwise correct, but was missing quantities or labels. A "wrong" picture has boxes that are the wrong relative sizes. Figure 1C shows an example where the box for the magazine cost (top box) is the same size as the box for the poster cost (bottom box) when, in fact, the magazine cost is bigger than the poster cost.

An "abstract" picture is shown in Figure 1D. The boxes in Figure 1D violate the size preserving constraint. Whereas the CD cost is largest, it appears as the smallest box (the top one). However, some students correctly interpreted these extra boxes (labeled —12 and —8) as, in essence, having a negative size.

A potential advantage of the abstract picture is that it may incrementally move students toward the kinds of abstract inferences needed for symbolic algebra transformations. On the easier Cans and Beanie problems, the 7 solutions employing an abstract picture were all correct. However, one disadvantage of the abstract picture is that without the size-preserving cues, students can easily confuse the operations that need to be performed and, for instance, subtract when they should add. This confusion led 4 of the 10 students who used an abstract picture on the CD problem to an incorrect answer. Further, even among the 6 students whose abstract picture led to a correct solution, there is evidence of confusion. Notice the arithmetic on the left in Figure 1D where the student incorrectly subtracts 20 from 46 rather than adding 20 and 46. The student abandons this approach when he notices that 3 does not divide evenly into 26. This correct solution may not have come from understanding, but from a shallow school heuristic that problems usually come out even.

Production Rule Model of Picture Algebra

We performed a production-rule analysis of typical correct and incorrect student solutions to the three problems. Table 2 shows examples of key productions.

Production Trace of Cans Solution

The correct solution to the Cans problem with a size-preserving diagram (see Figure 1A) is traced with 13 productions. These productions are the same ones needed to solve a more-than problem dealing with two unknown quantities and thus we would expect good transfer from class instruction. To process 3 unknown quantities rather than 2, some productions are executed multiple times. When drawing a size-preserving picture the model first has to draw a "base" box (P2a in Table

Table 2. Picture Algebra Production Rule Examples

P0a: Change-less-than-to-more-than If goal is to draw boxes to represent $=Q1$ is $=X$ less than $=Q2$ then set goal to draw boxes to represent $=Q2$ is $=X$ more than $=Q1$
P0b: Change-less-than-to-more-than-negative If goal is to draw boxes to represent $=Q1$ is $=X$ less than $=Q2$, then set goal to draw boxes to represent $=Q1$ is minus $=X$ more than $=Q2$
P2a: Draw-base-box-more-than If goal is to draw boxes to represent $=Q2$ is $=X$ more than $=Q1$ and no box has been drawn then draw a first box for $=Q1$
P3c: Draw-comp-box-equal-part-repair If goal is to draw boxes to represent $=Q2$ is $=Y$ more than $=Q3$ and first box for $=Q2$ with the size $=S1$ is drawn and no box for $=Q3$ has been drawn then draw a first box for $=Q3$ with the size $=S1$
P6a: Check-equal-size-boxes-with-extra If goal is to solve a problem with a box diagram and there are equal-size boxes and the value of an extra box for $=Q1$ is $=X$ and the box with value $=X$ has not been removed then set goal to remove the extra box

2). This box represents the 8th grade cans. Other productions draw "equal-part" boxes for the equal parts of the 6th and 7th cans and "extra-part" boxes for the 9 and 17. The final production in the representation phase draws and labels the bracket with the total 227.

At this point, the solution phase begins with production P6a, which sets a goal to remove an extra box. This production fires twice in the Cans solution, once with $=Q1$ set to 6th grade cans and $=X$ to 9 and a second time with $=Q1$ set to 7th grade cans and $=X$ to 17. Once all quantities represented as extra boxes (i.e., 9 and 17) are subtracted from the total quantity (227), further productions find the base quantity by dividing the new total (201) by the number of equal-size boxes (3). The model finishes with productions for finding the other two quantities by adding the extra box values (9 and 17) to the value of the base quantity (67).

Production Trace of Beanie Solution

The key to the model's solution of the Beanie problem is production P0a that converts a less-than relation to a more-than relation. Once the model sees "Robin has 6 fewer beanie babies than Angie" as "Angie has 6 more beanie babies than Robin", it can solve the problem just as it would a more-than problem. Students' relatively good performance on the Cans and Beanie problems is consistent with a production rule transfer analysis (Singley & Anderson, 1989). Relative to the familiar two-quantity, more-than problems students were instructed on, only repetitions of already known

productions are needed for the Cans problem and only one new production is needed for the Beanie problem.

Production Traces of CD Solutions

It turns out the simple less-than to more-than transformation performed by P0a does not work so well for solving the CD problem. A production rule trace of the incorrect solution to the CD problem in Figure 1C illustrates this point. As in the Beanie trace, the model begins by firing P0a to convert "price of magazine is \$8 less than the price of CD" to "price of CD is \$8 more than the price of magazine". It then draws the single smaller box for the magazine cost (top of Figure 1C, but without 8 inside) and the equal-part and extra-part boxes for the CD cost (first two boxes in the CD row, without the 12 box or the first 8 label). The representation is correct at this point, but after converting "the price of poster is \$12 less than the price of CD" relation to "the price of CD is \$12 more than the price of poster" the model has trouble.

If the model only had the productions needed for the Cans and the Beanie problem, it would reach an impasse here. Usually the smaller base of the more-than statement (Poster in this case) has already been drawn and there are productions for drawing the equal-and extra-parts of the larger quantity (CD). However, in this case, it is the smaller box (Poster) that has not been drawn. Our model predicts that students reach an impasse at this point and must implement a "repair" (VanLehn, 1983). The production P3c in Table 2 represents a result of this repair. It draws a base box for the Poster cost that is the same size as the equal-part of the CD cost. Next, an over-general production adds an extra box to the CD row for the "12 more". This production is over-general because it is missing a constraint to check that an extra box has not already been drawn (the middle 8 box in the CD row). The model continues, like the student, to correctly compute values consistent with this incorrect representation of the problem.

With only one production difference from the Cans and Beanie problems this solution is a relatively easy transfer. This provides an explanation for the frequency of this odd incorrect solution strategy. 8 of 34 students drew pictures for the CD problem like the one shown in Figure 1C with two extra boxes in the CD row.

Students found two ways to be successful on the CD problem. Figure 1D shows an example of one of these ways. The model again starts by converting the given less-than relations to more-than relations, but not by changing the position of the quantities in the relation, but by negating the difference value (P0b in Table 2). For example, "price of magazine is \$8 less than the price of CD" is converted into "price of magazine is - \$8 more than the price of CD". The model then draws an abstract diagram with an extra box in the Magazine

row that has a negative value. New productions are needed to deal with extra boxes with negative values. One of these productions removes an extra negative box by adding the absolute value of the box to the total ($46 + 12$ and $+ 8$). A similar production is needed in the final steps of the solution to combine these negative values with the unknown value (22).

A second approach to the CD problem involves directly representing the less-than relations in the picture (see Figure 1B). In this approach, the larger CD cost remains the base quantity in both relations. That the magazine cost is \$8 less is represented by labeling the space between the right end of the Magazine bar and the right end of the Poster bar. (It would be better if the student had not put a box around the 8 as this box implies the size of the Magazine cost includes this 8 when it does not.) Only one student on the CD problem drew a picture that was close to size preserving.

Both of the correct solution strategies for the CD problem involve more new productions (4 and 7) than the incorrect solution strategy (1). While the abstract picture strategy involves fewer new productions (4) than the size-preserving strategy (7), there are other relative advantages of the size-preserving strategy.

The new productions required for the size-preserving strategy are mostly straightforward analogies with existing productions, where less-than is substituted for more-than. More importantly, this strategy provides more reliable perceptual support for inferences. To get three equal bars, one must fill in the empty space to the right of the Magazine and Poster boxes (see Figure 1B). This "filling in" is a perceptual cue for addition. In contrast, in the abstract picture (see Figure 1D), the perceptual cues suggest "removing" or subtraction and, as we saw, many students fell for or were distracted by this cue. To succeed with this strategy, students have to do explicit symbolic processing to infer that taking away a negative is the same as adding.

An important consequence of this analysis was the recognition that students should be instructed *not* to draw boxes around extra missing parts (see the —8— and —12— in Figure 1C), but to use a double-headed arrow or bracket to mark the empty space.

Discussion

The Picture Algebra strategy benefits from a number of positive features of diagrammatic representations: grouping to facilitate search, reducing the need for symbolic labels, and substituting intuitive perceptual inferences for more difficult logical inferences (Larkin & Simon, 1987). The potential value of this strategy is evidenced by the observed success of 6th grade students on algebra-level problems that are quite difficult for many older students.

Teachers always encourage students to check their answers and students appear more likely do so when

using Picture Algebra (Fig 1B,C,D) than when using other strategies. We speculate that by evoking students' spatial intuitions, the pictorial representation puts students in a "sense making" mode that leads to greater self-monitoring (cf., Kalchman, Moss, & Case, 2001).

However, instruction based on pictures is not a panacea. Although pictures may facilitate students' reasoning and learning, it is not trivial for students to learn to use such representations flexibly and with understanding. Not all students using Picture Algebra engaged in sense making. Some made errors typical of equation solving (e.g., subtracting when they should add) and failed to catch them even with the visual support of the picture (cf., Lewis, 1989).

Although students performed relatively well on problem demands presented individually in the Cans and Beanie problems, they had much greater trouble with the CD problem that combined both demands. Our production rule analysis provides a detailed explanation for why this problem is significantly more difficult. The difficulty arises from the order in which the quantities are related to each other and potential traps from inappropriately selecting a "base" quantity.

A novel prediction of our model is that a 3-quantity more-than problem of the form "A is X more than B and A is Y more than C" should be almost as difficult as the CD problem (a 3-quantity less-than problem). This prediction follows from the fact that the model essentially converts the CD problem into this form. Similarly, the model predicts that a 3-quantity less-than problem of the form "A is X less than B and A is Y less than C" should actually be relatively easy, more like the Cans problem. The generation of such predictions has pushed us to rethink and improve our curriculum design to better address the previously hidden skills revealed by our production rule analysis.

This paper reports on theoretical and empirical steps toward answering the following research questions:

1. Can instruction on the use of Picture Algebra help younger students gain entry into algebraic reasoning sooner than direct instruction on formal algebra?
2. Can instruction on Picture Algebra help younger students build a foundation that will improve and accelerate later learning of formal algebra?

Because of the complexity and cost of performing classroom experiments that could directly address these questions, these questions are excellent candidates to test the applicability of cognitive theory. Our goal is to employ cognitive theory and lower cost empirical studies to provide strong arguments for and/or against these claims. With such arguments in hand, we are better prepared to assess the potential benefit of a costly classroom experiment and, perhaps more importantly, facilitate the design of an instructional method that is most likely to be successful.

Abstract

The effects of adjustments in teaching strategy and of paralanguage information in speech sound on the meaning acquisition process were determined by means of an experiment in which the game "Pong" was played by a team of two subjects. One subject (the teacher) coached the other one (the operator), instructing the operator in which direction to move the game paddle and when to hit the "ball." However, the teacher's speech was rendered linguistically incomprehensible. Three phenomena were observed. First, the use of a high-pitched voice by the teacher caused the operator to pay more attention to her/his actions. Second, meaning acquisition could be regarded as a reinforcement learning process based on a multi-reward system (i.e., one for successful game action and a different one from the teacher's high-pitched voice for the wrong action). Third, the subjects adapted to each other; that is, they learned to respond more appropriately to each other's behaviors (we call this **mutual adaptation**). These three phenomena are thought to play important roles in the acquisition of meaning from incomprehensible speech.

Introduction

How do people who speak different languages learn to communicate? How do they acquire the meanings of each other's speech? One way to interpret the meaning-acquisition process is to view it as statistical learning in which a certain speech sound is linked to the situation in which it was given. Several research groups have constructed general meaning-acquisition models based on this simple interpretation (for instance, Siskind, 1996). Testing of these models demonstrated that the word meanings can be acquired using statistical learning methodologies.

Some groups have investigated the teaching of word meanings to robot agents, which can move by themselves (Billard et al., 1998; Roy, 1999). For example, Kaplan (2000) showed that a four-legged robot could learn the names of a dozen objects shown in front of its "eyes" (camera) by the experimenter during its action experiences.

One study in particular demonstrated that an autonomous agent could learn not only the meanings of instruction words but also the meanings of evaluation instructions such as "good" and "bad". Suzuki et al. (2002) developed a learning agent model that could learn the

meanings of words and evaluation instructions during its action experiences.

A large variety of learner models have thus been demonstrated. Siskind's learner model was a computer that processed string inputs; Kaplan's was a four-legged robot that could learn object names; and Suzuki's was a computer agent that could move by itself in a virtual environment. In contrast, only one type of "teacher" has been demonstrated, one who gave instruction based on unchangeable rules. In real life, however, good teachers adjust their teaching strategy to fit the learner's mode of learning. For example, a caregiver will speak to a preverbal infant using only simple words. Then, when the infant starts to speak, the caregiver will start to use more complex words and speak in different ways. So far, there have been no studies on how dynamically adjusting the teaching strategy affects the meaning acquisition process.

Investigating the process involved in acquiring meanings from speech sounds requires investigating the effects of not only phoneme information, which can be expressed using characters and text, but also of paralanguage information, such as prosody, speech speed and loudness, which cannot be expressed using characters and text. The effects of paralanguages information have been studied in various acoustic studies. For example, many studies have focused on the turn-taking mechanism (Pirrehumbert & Hirschberg, 1990) and emotional recognition (Hirose et al., 1997). However, so far, there have been none on the effect of paralanguage information on the meaning acquisition process.

We investigated the effects of adjustments in teaching strategy and of paralanguage information in speech sounds on the meaning acquisition process. We carried out a communication experiment, in which a team of two subjects played "Pong". One subject (the teacher) coached the other one (the operator), instructing her/him in which direction to move the game paddle and when to hit the "ball." However, the teacher's speech was rendered linguistically incomprehensible. We observed how the listener acquired the meanings of the given instructions. For the paralanguage information, we focused on prosodic information, because data extraction should be easier and the possibility of the engineering realization is higher. The results provide a new point of view about meaning acquisition process and can be used to develop

Figure 1: Game Environment

Figure 2: Different Display Settings

basic technologies for constructing interactive robots that can understand what is said to them, enabling them to communicate smoothly with people.

Experiment

Method

The experimental game environment is depicted in Figure 1. The two subjects were placed in separate rooms: the teacher in Room A, and the operator in Room B. The teacher's spoken instructions to the operator were transmitted through a low-pass-filter (LPF) and played over a speaker in Room B. The LPF masked the phoneme information, which included the symbolic elements of speech sound; it did not affect the prosodic elements. This means that the operator could hear only the prosodic information; s/he could not understand the teacher's instructions as meaningful linguistic information. They were simply noisy sound.

The team playing the game was awarded 10 points each time the operator hit the ball, and 10 points were deducted each time s/he missed it. As shown in Figure 2, the game display of the teacher differed from that of the operator: the teacher's display showed the ball, whereas the operator's did not. The operator could see only her/his paddle and the score information, indicating whether s/he had hit or missed the ball.

Even though the instructions were masked by the LPF, the operator still might be able to guess which instruction was given based on the number of phonemes heard. For example, "right" and "left" in Japanese

are *migi* and *hidari*, which have different numbers of phonemes. The display of the teacher and operator were thus made symmetrical with respect to the dashed line in Figure 2 to prevent biasing of the results.

Subjects

Eleven teams, each composed of two subjects (Japanese, 20-28 years old, 18 men and 4 women), participated in the experiment. The members of each team were required to know each other. One additional team participated in two control experiments: one without LPF and one without instructions.

Procedure

First, the experimenter explained to the subject team (one operator and one teacher) that the purpose of the experiment was to score as high a total score as possible by working together. Then, the experimenter let the team hear a vocal sample, with and without LPF masking, to demonstrate the filter's effects. The experimenter did not mention the differing displays.

The test was then started. Each team played two consecutive 10 minutes games, with 3 minutes of rest between them. The roles of teacher and operator were fixed, and the team members did not have an opportunity to talk face to face and share information.

Results

To evaluate team performance, values were assigned to two types of actions, moving the paddle and hitting the ball. For each move action, if the operator moved the paddle in the teacher's intended direction, **Correct Direction Value (CDV)** was assigned one point; if s/he moved it in a different direction, CDV was assigned zero point. For each hit action, if the operator hit the ball, **Hit Value (HV)** was assigned one point; if s/he missed it, HV was assigned zero points. Testing statistical hypothesis using binominal distribution was used to group the subjects, and actually the teams were divided into three groups as follows.

Group 1 Average CDV less than 0.8 point.

Group 2 Average CDV more than 0.8 point; Average HV less than 0.7 point.

Group 3 Average CDV more than 0.8 point; Average HV more than 0.7 point.

Table 1 shows the average values of the last ten hit and move actions for the three groups. Out of the 11 teams, two failed to understand any instructions (Group 1). Among the nine remaining teams, five succeeded in moving the paddle in the direction the teacher intended but could not hit the ball well (Group 2). We call this achievement "learning to recognize direction instructions." The four remaining teams could move to the teacher's intended position. We call this achievement "learning to recognize distance instructions"(Group 3).

Table 1: Correct Direction Value (CDV) and Hit Value (HV)

Group	(CDV, HV)
Group 1 (2 pairs)	(0.5, 0.5), (0.3, 0.2)
Group 2 (5 pairs)	(0.9, 0.3), (1.0, 0.2), (1.0, 0.5) (0.8, 0.6), (1.0, 0.6)
Group 3 (4 pairs)	(1.0, 0.9), (1.0, 0.7) (1.0, 0.7), (0.9, 0.8)
*control	no instructions (0.5, 0.2), (0.4, 0.3) without LPF (1.0, 0.7), (1.0, 0.8)

Figure 3: Trend in Comprehension of Instructions for Typical Group 3 Team

Table 1 shows that the values of two teams in Group 1 were the same as those for the control pair when they did not received instructions. Most of the teams in Group 2 and Group 3 had an average score between that of the two control settings, and some teams in Group 3 scored as high as the control group without the LPF.

We used **Comprehension of Instructions Value** to evaluate the operator's comprehension of the instruction. This value was assigned 0 points if the paddle was moved in the wrong direction, 1 point if it was moved in correct direction but the ball was not hit, and 2 points if it was moved in the correct direction and the ball was hit. The value for a typical team in Group 3 are plotted in Figure 3. The curve shows the moving average of the ten hit opportunities. When the curve was between 0 and 1 point, the operator is thought to have focused on understanding the direction instructions; when it was between 1 and 2 points, the operator is thought to have focused on understanding the distance instructions. The operator more quickly learned to comprehend the direction instructions than the distance ones. We investigate the processes of these two learning phases in terms of the prosodic elements of the instructions, the movement of the paddle, and the variety of instructions given. We focused on the pitch of the teacher's voice, which, among the prosodic elements, had the strongest relationship with the meaning of the instructions. As shown in Figure 6, when the pitch was increased, the operator tended to suddenly changed her/his action.

Phase 1: Focused on Direction

The operator on nine of the 11 teams learned to comprehend the direction instructions. A particular teaching/learning process was used by most of the nine teams. First, the teacher gave a wide variety of instructions to the operator, e.g., "move to the center of the display", "move a bit right", etc. The pitch curve of this initial teaching is depicted on the left side of Figure 4. It would have been difficult for the operator to discriminate between the "ue, ue, ue..." (up, up, up...) instructions for the right direction and "shita, shita..." (down, down...) instructions for the left.

As the teaching continued, the teacher gradually decreased the variety of instructions, typically converging on only two, such as *ue* and *shita*. In contrast, the teachers on the unsuccessful teams did not decrease the variety and continued to use a wide variety (Figure 5). Decreasing the variety of instructions apparently makes it easier to understand direction instructions.

In conjunction with this gradual decrease in the variety of instructions, the difference in the pitch curves of these two instructions became more distinct. Most teachers started to repeat the instructions, e.g., "ueueue..." and "shitashita..." The former was audible as one long, continuous voice, while the latter sounded like many choppy utterances (see the right side of Figure 4).

Here, the operator learned to recognize the type of instructions according to the differed sounds. At the same time, subjects were ready to make her/his paddle actions correspond to them. The operator then started exploring this correspondence by trial and error. If the operator succeeded in hitting the ball, even by chance, s/he learned to associate the given instruction with her/his last action. The teacher elicited a correct response by using higher vocal tones (depicted in the circle in Figure 6). When the pitch at a certain point in a series of teaching voices was about 20 [Hz] higher than the pitch at the onset, and when this higher pitch continued for at least 500 [msec], the operators intuitively recognized this as a warning from the teacher. Specifically, when the operator heard instructions delivered at a higher pitch, s/he recognized that her/his current action was wrong and modified it accordingly. Therefore, high-pitched vocalizations in Phase 1 served as a negative reinforcement of the operator's last action. The operators thus learned to compre-

Figure 4: Pitch Curves of "Ue" and "Shita" in Phase 1. Left: 250 sec, Right: 540 sec

Figure 5: Variety of Instructions used by Successful/Unsuccessful Teams

Figure 6: High-Pitch Element in Teaching Voice

hend the teacher's instructions by reinforcement learning based on a positive reward (hitting the ball) and a negative one (hearing a high-pitched voice).

Learning to recognize the instructions during Phase 1 was due not only to the teacher's efforts but also to the operator's action. The actions of operators on the successful teams were initially reluctant, concentrated on inferring the teachers' intentions from the given instructions. The operators started reacting actively after they inferred the intentions. Their actions thus indicated their comprehension of the given instructions. The operators on the unsuccessful teams were also reluctant at the beginning of the experiment, but over time they started moving actively, even though no instructions had been given: the operators seemed to disregard the instructions. In this case, the operator's actions did not indicate any comprehension of the instructions.

Although at a first glance it seems that meaning acquisition was achieved only by the operator adapting to the teacher's instructions, the teacher actually changed the instructions and method of delivery based on the operator's comprehensions, which was judged from the operator's reaction. The subjects actually learned to respond more appropriately to each other's behavior, so that meaning acquisition was a mutual adaptation pro-

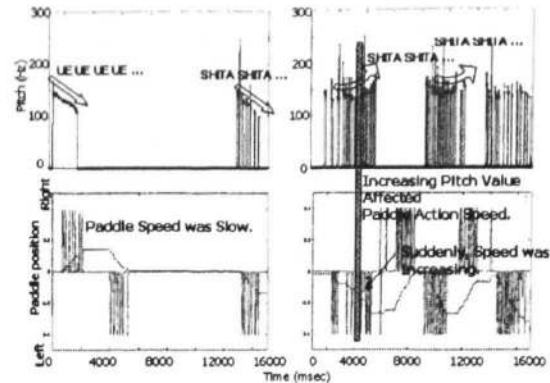

Figure 7: Pitch Curve of "Ue" and "Shita" in Phase 2. Left: 1070 sec, Right: 1270 sec

cess.

Phase 2: Focused on Distance

In this "Pong" game experiment, learning to recognize the direction instruction was not sufficient for achieving a high score. The distance information was also needed to consistently hit the ball with the paddle. Of the nine teams that learned to recognize the direction instructions, four were able to recognize the distance instructions. These four teams exhibited two distinct approaches to learning to recognize distance instructions. One team used the "stop" instruction, and three teams did not.

"Stop" Instruction Used One team developed a common understanding of the "stop" instruction before developing one for direction instructions. The sound of "stop" has a short, skipping sound, so it was not difficult for the operator to understand this literally as "stop". This team then developed a common understanding of direction instruction, like the repetitive "ueueue..." for move right and "shitashita..." for move left. In the case of using of "ue", the teacher had to give repetitive instructions; otherwise the independent usage of "ue" was recognized as a choppy sound, meaning the opposite (left, "hidari") direction. Therefore, the instruction to move right had to be repetitively elongated to avoid confusion with the usage of independent "ue". Otherwise, the operator tended to go past the teacher's intended position. When this "overrun" problem occurred, the teacher started saying "ueueue, stop, shitashita" to bring the operator back to the intended position. Finally, when the teacher said "stop" after a repetitive "ueueue...", the operator immediately reversed direction so as not to overrun the teacher's intended position. Thus, the operator took the "stop" instruction as the literal meaning or as meaning "go left". This is a typical example of mutual adaptation in this experiment.

"Stop" Instruction Not Used The three teams that did not use the "stop" instruction learned to recognize direction instructions in a manner similar to that of the other team. In a typical case, after teaching the operator to learn to recognize direction instructions, the teacher pitched her/his voice higher at the onset of utterance and lower at the end, i.e., the intonation decreased, as shown on the left side of Figure 7. When the distance from the paddle appeared to the teacher to be too short, the teacher gradually increased the pitch at the end of the utterance. Specifically, the teacher increased the pitch at the end of the instructions utterance when a long distance appeared to be needed (see the right side of Figure 7), whereas s/he reduced it when the distance appeared to be short. In this way, the teacher controlled the operator's action by increasing or decreasing the pitch at the end of the instruction utterance. High-pitched utterances spurred the operator's actions, which can be broadly interpreted as drawing the operator's attention to her/his actions.

Even among the nine teams who learned to recognize the direction instructions, five were unable to learn to recognize the distance instructions. The teachers on the successful teams came to realize that repetitive instructions were important to learning to recognize the direction instructions. They did this by observing the operators' actions. The teachers on the unsuccessful teams apparently did not come to this realization and were thus perplexed when the operators headed in the opposite direction when an "ue" instruction was given.

Comparison of the successful teams with the unsuccessful ones in the two meaning acquisition phases showed that the team members had to learn to respond appropriately to one another's behaviors to acquire a high score. The series of dynamic behaviors shown by the successful teams can be regarded as **mutual adaptation**.

Three points in particular were observed for the successful teams.

1. The use of a high-pitched voice by the teacher caused the operator to immediately focus on her/his action.
2. The operator learned to recognize the teacher's instructions by reinforcement learning composed of a positive reward (hitting the ball) and a negative one (hearing a high-pitched voice).
3. During the meaning acquisition process, mutual adaptation was observed. That is, team members learned to respond more appropriately to each other's behaviors.

Thus, paralinguistic information functioned as a negative reward in the reinforcement learning process, and the teacher's adjustment in teaching strategy was observed as a mutual adaptation process. Paralinguistic information and adjustment in teaching strategy thus play important roles in learning to recognize unknown teaching utterances.

Discussion

Effects of Adjusting Teaching Strategy

In this experiment, we observed a mutual adaptation process: the two members (the teacher and operator) learned to respond more appropriately to each other's behaviors. This study did not, however, consider how substantial differences between dynamic and static teaching strategies affect the meaning acquisition process. The actual effects of the teacher's dynamic instructions on meaning acquisition are thus unclear. We plan to investigate this effect by carrying out additional experiments in which we will control the behavior of the teachers. In any case, we observed that the teachers on the successful teams adjusted their teaching strategy according to the operator's comprehension of the given instructions. This observed behavior differs from one-directional, or fragmented communication aspect, such as that in the code model of Shannon & Weaver (1949). Wiener et al. (1972) argued that a symbol exchange model, which is a code model, is a primitive model of communication. Sperber and Wilson (1986) refuted this argument and argued instead that their "relevance theory" is a primitive model of communication. Although this theory might approach the essence of human communications and thus overcome the bottleneck of the code model: inferences in this theory can only be made using simple "deductive" inference rules (Kimura, 1997). Therefore, this theory is equivalent to the code model if we regard the inference "rules" as a complicated "code". This theory, moreover, has another problem: technical terms in the theory are not connected through physical existence. These unsolved problems reduce the theory's ability to explain actual communications.

In our experiment, it seemed at first that only the operator adapted to the teacher's behavior, because only the teacher could give spoken instructions. However, during the process of establishing communication, we observed that not only did the operator adapt to the teacher's behavior, the teacher adapted to the operator's behavior. While it is not uncommon for a teacher, who is a usually an information transmitter, to sometimes become an information receiver, in our experiment, the transmitting and receiving occurred simultaneously. This observed phenomenon cannot be explained by the code model. Thus, the results of our experiment suggest that the actual communication process cannot be expressed using a one-directional communication view like the code model. Instead, a mutual adaptive view that cannot be decoded into one-directional relationships is needed.

Effects of Paralinguistic Information

In this experiment, we observed that the use of a high-pitched voice by the teacher caught the operator's attention. In general, the pitch of a speech sound decreases as the utterance draws to the end. If the pitch deviates from this pattern, the listener immediately catches the change. The observed function of the high-pitched voice in our experiment can be explained by this "prominence mech-

anism." Each team, regardless whether it was successful or not, actually made use of this function, which might be a universal trait among humans.

An infants' salient attention to a motherese voice, as revealed in various cognitive development studies, suggests that sensitivity to prosodic information is either an innate function or is learned just after birth. From our results, it might be said that infants react to the prosodic information in the caregiver's speech, not to the phoneme information. The meaning acquisition process observed in our experiment can be regarded as reinforcement learning with multiple-rewards, and the high-pitched voice among the various types of prosodic information functioned as one of two rewards. That is, prosodic information affects the meaning acquisition process at some basic levels. Thus, it can be assumed that the infants' language acquisition process and the meaning acquisition process in our experiment are similar in both depend on receiving prosodic information before acquiring the actual meanings of speech or teachings. Further research should reveal how this assumption is related to the language acquisition processes.

Application Based on Results

From the results of our experiment, we conclude that paralinguistic information and adjustments in teaching strategy play important roles in learning the meaning of unknown utterance. If an autonomous robot had such abilities, it should be able to learn the meanings of human utterances and thus be able to communicate with people smoothly. In the traditional method of developing an interactive robot system, the designer needs to map specific utterance to the robot's functions. However, by applying the phenomena observed in our experiment, the designer need not to define such a mapping *a priori*, but simply needs to define "high-pitched voice = negative reward" and "successful action = positive reward". From these definitions, the robot can learn by itself the mapping between unknown utterances and its possible actions by using a reinforcement learning process based on the two types of rewards. Consequently, the robot will be able to adapt to its owner by trial and error, and over time the robot and owner can create an intimate relationship.

Conclusions

A communication experiment was carried out to observe the effects of a teacher's adjustment in teaching strategy and of paralinguistic information in terms of learning the meanings of unknown utterances. An adjustment in teaching strategy was observed as a mutual adaptation process, in which the two subjects on a team learned to respond more appropriately to each other's behavior, and paralinguistic information was observed to function as a negative reward in a reinforcement learning process for meaning acquisition. These two phenomena thus play important roles in learning the meaning of unknown utterances.

Abstract

We propose that qualitative physics can provide an important component of natural language semantics. Specifically, we describe how qualitative process theory can be recast in terms of frame semantics, as used in the Berkeley FrameNet project. This reformulation is important because it could allow the techniques of qualitative reasoning to be harnessed for natural language understanding and it expands the range of phenomena that can be described in NL semantics. We show that these ideas can account for a large percentage of a small corpus of explanatory text, and that they support the construction of QP models from such texts.

Introduction

Understanding the semantics of natural language is a central problem in cognitive science. Such an understanding must connect fundamentals of our conceptual structure to their realizations in linguistic forms, and thus must draw upon both insights about language and about conceptual structure. Significant progress is being made on the language side, with projects such as FrameNet (Fillmore et al 2001) developing broad systems that capture aspects of the meaning of words and linguistic constructions in terms of *frame semantics* (Fillmore & Atkins, 1994). Significant progress is also being made on understanding aspects of human conceptual structure, for example, the work carried out in the qualitative reasoning community. Qualitative reasoning focuses on the representations necessary to reason about the physical world, ranging from everyday phenomena to the work of scientists and engineers. While many QR efforts are aimed at applications, some efforts are aimed directly at modeling human reasoning about physical systems (cf. Bredeweg & Schut, 1991; Kuipers & Kassirer 1984; Kuipers et al 1988; Forbus & Gentner 1986, 1997). Ultimately these two lines of investigation, natural language semantics and the understanding of human conceptual structures, need to join forces. In the words of the FrameNet team¹: "In the end it will be necessary to express frame notions in some formal knowledge-representation language which will allow valid inferences to be drawn from frame semantic representations of sentences, or which

can serve in a precise way in the development of a cumulative representation of the content of an ongoing discourse."

This paper is a first step in linking these investigations. We propose that qualitative process theory (Forbus 1984) can provide such a knowledge representation language for aspects of frame semantics concerned with continuous parameters and continuous causation. QP theory concerns the structure of a class of physical theories, and has been successfully used in a variety of reasoning systems (Forbus, 1996). The hypothesis is that many mental models of physical phenomena can be expressed in this formalism. QP theory has been used to develop a wide range of models of phenomena, including economic and medical models in addition to physical models. This makes it an excellent candidate for a component in a larger system of natural language semantics.

We begin by building a theoretical bridge between QP theory and frame semantics, as exemplified in FrameNet. We briefly review the relevant aspects of QP theory and show how they can be recast in terms of frame semantics. This recasting provides a means for defining frames for physical processes and relationships involving continuous parameters. We illustrate how these ideas can be used to extend a natural language semantics by an analysis of flow.

With the theoretical bridge in place, we provide empirical support for it via a corpus analysis of an explanatory text. This analysis provides evidence concerning two questions. First, we explore how much of the explanation these frames can account for. Second, we analyze whether a qualitative model can be reconstructed from the text using these frames. Finally, we discuss some new issues raised by this approach and plans for future work.

Qualitative physics in frame semantics

We begin by recasting QP theory in terms of frame semantics, as used in FrameNet. We review the ontological assumptions underlying QP theory and their implications for the organization of the frame system. Next we discuss physical processes and their occurrences, followed by an analysis of how qualitative mathematics is expressed. We conclude this section by showing that this analysis is compatible with analyses of overlapping phenomena already in FrameNet.

¹ The FrameNet project's home is the International Computer Science Institute in Berkeley, CA. A detailed description of the project can be found at <http://www.icsi.berkeley.edu/~framenet>

Ontological assumptions

In QP theory, physical changes in continuous properties are caused by *physical processes*. Examples of physical processes include kinds of flows (e.g., heat, liquid, gas), phase changes (boiling, freezing), and some aspects of motion. Ontologically, physical processes serve as the mechanisms of physical causality: All naturally occurring changes (and many of the indirect effects of the actions of agents) are ultimately caused by the activity of one or more physical processes. Instances of physical processes exist when an appropriate configuration of *participants* occurs. Such process instances are *active* over any span of time for which their *conditions* hold. When a process instance is active, its *consequences* hold. For example, two thermal entities (i.e., having the continuous property *heat*) that are thermally in contact give rise to two instances of heat flow, one in each potential direction. Whether or not either of these is active depends in turn on the relative temperatures between the two bodies.

The consequences of a physical process are of three types. First, there are *direct influences* that represent the direct effects that a physical process has on the world. For example, heat flow causes the heat of the source of the flow to decrease while increasing the heat of the destination. Second, there are other dynamical properties defined, including new parameters and causal laws, which describe how changes propagate through continuous properties. For example, the rate at which heat flows is a continuous property, and it is determined by the difference between the temperatures. Third, other properties that hold while the process is occurring, such as appearance information, can be consequences. In everyday boiling, for instance, one typically sees bubbles.

Two key conceptual advances in qualitative modeling are the insights that (1) many important kinds of reasoning about dynamical systems can be done without numerical information or mathematical models and (2) qualitative relationships can be formulated which explicitly capture patterns of human causal reasoning. These causal connectives are summarized below; see (Forbus 1984) for details. The values of continuous parameters tend to be expressed in comparative terms, via ordinal relationships constraining a parameter with respect to other relevant properties. If an object participates in process instances of heat flow, for example, then its temperature is defined in terms of its relationships with the temperatures of the other objects participating in those heat flows.

This summary highlights three important properties of QP theory that makes it potentially a valuable component of natural language semantics. First, the notion of physical process it defines is psychologically plausible. Descriptions of physical processes are abundant in language concerning physical phenomena, and are routinely used in metaphors (cf. Lakeoff 1980, Gentner et al 2001). Second, the causal account QP theory provides is consistent with human causal explanations in most physical domains (Forbus & Gentner 1986, 1997). Third, the abstract level of information that

qualitative representations support seems a natural fit for the level of specificity commonly found in natural language descriptions of physical principles and situations. One does not need to understand differential equations or carry out detailed simulations to understand physical metaphors ("her anger mounted until she boiled over").

Recall that in frame semantics, meaning is expressed in terms of systems of structured representations, *frames*, whose parts (called *frame elements*, abbreviated FE) are bound to parts of a text and have associated with them inferences that provide meaning (Fillmore & Atkins, 1994). The packaging of physical knowledge and principles in QP theory (inspired in part by Minsky's (1975) notion of frames) suggests a natural alignment with frame semantics. There is a basic *physical process* frame, whose structure provides the fundamental aspects of physical processes. Subframes describe particular categories of physical processes, with differences in their participants and consequences being the differentia that set them apart. Instances of these frames are combined with frames from other aspects of the semantics to create the frame system describing the meaning of a text. The qualitative causal mathematics of QP theory is expressed through another collection of frames. In addition to their role in physical process descriptions, these qualitative causal frames can be used for other domains with continuous parameters, such as economics or metaphorical extensions of physical concepts. The next three subsections outline these frame systems.

Processes and their occurrences

The *PhysicalProcess* frame involves four types of FEs:

- *Participant* specifies one of the participants in the physical process. Example: in "Heat flows from the hot brick to the cool room", "hot brick" and "cool room" are *Participants* in an instance of the *HeatFlow* frame.
- *Condition* specifies one of the conditions under which the process is active. Example: in "Heat flows from one place to another because the temperature of the two places is different." the *Condition* is the difference in temperature values (see *ordinals* below)
- *Status* specifies whether or not the process is active. Example: In "The radiator leak was stemmed by shoving a cloth into it." The word *stemmed* suggests that a flow which was enabled is now stopped. We say that the *Status* is *active* when the process is occurring, and *inactive* otherwise.
- *Consequence* specifies one of the direct consequences of the physical process. Example: In "Water flooded into the room when the valve broke." the liquid flow into the room has as one of its *Consequences* an increase in the amount of water in the room.

These frame elements can be directly mapped to the formal models that QP theory supports. For a process type or instance, the set of participants collectively define the collections of entities it occurs among. The union of the conditions is the set of conjuncts that comprise the necessary and sufficient conditions for it to be active. The

set of fillers for the consequences FEs constitute its direct consequences.

Our analysis of the syntactic realizations of these frame elements, and the others reported here, is work in progress, and we plan to analyze a much larger corpus to ensure that our results are robust. That, plus space limitations, will limit our discussion of syntactic realizations to a few stable highlights. Noun phrases that serve as the primary actor and object in a sentence tend to be participants, e.g., in "A hot brick loses heat to a cool room." "Hot brick" and "cool room" are participants. Certain frame elements already used in other FrameNet frames, e.g., *Source* and *Destination*, tend to be participants when a physical process is the actor. The patterns that indicate conditions include "Condition **causes** Process", "Process **occurs when** Condition", and "Process **depends on** Condition." For consequences, there are two cases: influences and other consequences. Influences are discussed below. The other consequences, since they can range over almost any physical statement in principle (e.g., appearances, sounds, etc.), are difficult to characterize concisely. Example indicators are occurrences of the FrameNet FEs of *Manner* and *Result*.

Parameters and values

Continuous properties are represented by the *Quantity* frame, which has the following elements:

- *Entity* specifies what this property is a property of. Typically this is unique. Example: "brick" in "the temperature of the brick"
- *QuantityType* specifies the kind of parameter that this is. Example: "temperature" in "temperature of the brick."
- *Value* specifies the numerical value of the property. This FE is optional. Example: "3" in "3 liters of water".
- *Units* specifies the physical units of the property. This FE is optional. Example: "kilograms" in "3 kilograms of lead".

Ds specifies how the parameter is changing and stands for "sign of the derivative". This FE is optional. Example: In "The temperature is increasing." the sign is expressed by the word "increasing" which would be mapped to the value of 1. While syntactic realizations for quantity types, values and units are fairly obvious, *Ds* manifests itself in the text many different ways, e.g. *-I* could show up as "falling", "decreasing", etc.

Values and units are often not explicitly stated or even filled in via default, but *Ds* and comparative statements about values are common. These are expressed via the *Ordinal* frame, which has the following FEs:

- *Q1*, *Q2* specify the quantities being compared. Either is optional. Example: "the coffee's temperature".
- *OrdReln* specifies the relationship between the values of the quantities. It must be one of $<$, $>$, $=$, \geq , \leq , \neq , *same-order*, or *negligible*. Example: In "Evaporation can be ignored" the word "ignored" refers to a negligible *OrdReln* of the rate of an evaporation process compared to other processes being described.

Ordinal relations provide a useful qualitative notion of value because they often serve as conditions for physical processes and states (e.g., flows occur when a driving parameter is unequal, equilibriums occur when opposing effects are equal). Syntactic realizations of ordinals are usually described via explicit comparisons (e.g., "*Q1* is greater than *Q2*") or as some type of comparative construction. One very common pattern is the use of ordered dimensional adjectives to set up a tacit comparison. For instance, from "hot brick" and "cool room", one knows an ordinal relationship involving their temperature due to the meanings of "hot" and "cool".

Qualitative mathematics and causality

The causal relationships between quantities are expressed via a qualitative mathematics that supports partial information about the nature of the connections between them. The basic frame is the *Influence*, whose FEs are

- *Constrained* specifies the dependent quantity, i.e., the effect.
- *Constrainer* specifies the independent quantity, i.e., a proximal cause for the constrained quantity.
- *Sign* specifies the direction, which can be + or -. It is expressed by words such as "up", "down", "greater", "more", "less" etc.

There are two subframes of the *Influence* frame, *DirectInfluence* and *Qprop*. These correspond to the QP theory primitives $I+/I-$ and $\propto Q_1/\propto Q_2$ respectively (Forbus 1984). While the two subframes share frame elements, the underlying semantics is quite different. For direct influences, the constrainer is combined via addition to other constrainers to determine (qualitatively) the derivative of the constrained quantity, and the sign indicates whether it is a positive or negative contribution to that sum. For *Qprop*, the *Constrained* is functionally dependent on the *Constrainer*, and perhaps on other properties as well, with the sign indicating whether the dependence is increasing or decreasing monotonic. This is the weakest distinction that enables changes to be propagated through causal laws.

As their common heritage suggests, in some cases the syntactic realizations of these two kinds of influences can be quite close. However, many cases are straightforward. Some realizations for *Qprop* include "Constrained **depends on** Constrainer." and "As Constrainer *Ds*, Constrained *Ds*." For example, "As the air temperature goes up, the relative humidity goes down" is clearly a *Qprop*, with *Constrained* = "relative humidity", *Constrainer* = "air temperature", and *sign* = -.

Syntactic realizations for *DirectInfluences* are more complex. In advanced texts one can find patterns such as "The rate of Constrained **depends on** Constrainer." but they do not seem common. In everyday texts explicit discussions of rates seem even rarer. Instead, *DirectInfluences* tend to occur in larger-scale patterns, often tied to a generalized notion of motion. For example, "Most water in the air comes from evaporation." is a

DirectInfluence, with Constrained = "water in the air",
Constrainer = "[rate of] evaporation" and Sign = +.²

Compatibility with existing frame semantics

One implication for semantics is that, in addition to the frames associated with QP theory per se, there will be a collection of subframes corresponding to particular kinds of physical phenomena, such as flows, motion, and phase changes. And indeed FrameNet already has an existing analysis of motion that is compatible with QP theory. The FEs of Theme, Source, Goal, and Path are finer-grained distinctions of the FE Participant in the general PhysicalProcess frame. In QP theory models of this kind of motion (cf. Forbus 1984), there is a quantity Position that is referenced to the Path from Source to Goal. A DirectInfluence frame with Constrained = Position and Constrainer = Velocity is a Consequence of the Motion frame. An Ordinal frame with Q1 = Velocity, Q2 = zero, and OrdReIn = ≠ is the Condition for the Motion frame. This compatibility is encouraging, since it means that the implications that can be drawn from qualitative reasoning could be made available in service of natural language understanding.

Example: An analysis of flow

Next we present an analysis of an important frame for physical phenomena, flow. We start with well-worked out ideas in the qualitative physics literature, using the framework above to recast them into frame semantics. This frame is used in our corpus analysis below.

The general Flow frame

The model of flow we are starting with is based on those in Forbus (1984). Several of the frame elements are specializations of Participant:

- *FlowSource* specifies the starting region of the flow.
- *FlowDest* specifies the region where what is flowing ends up.
- *FlowPath* specifies the path along which the flow occurs

These FEs determine the overall type of flow occurring:

- *FlowDriver* specifies the intensive quantity (e.g., something like pressure or temperature) whose difference at source and destination drives the flow.
- *FlowQ* specifies the extensive quantity (e.g., something like mass or heat) that is directly influenced by the flow. Optional.
- *FlowStuff* specifies the "stuff" which is considered to be flowing. Optional.

Typically texts mention either *FlowQ* or *FlowStuff* but not both. Many uses of the *Flow* frame are metaphorical from a

scientific perspective (e.g., heat is not a substance), but may be literal from a common sense perspective, depending on the language user's mental models. *FlowStuff* must be continuous in nature (hence *FlowQ* must exist, even if not explicitly mentioned) for the idea of flow to make sense.

There are two Condition FEs for *Flow*. The first is an Ordinal, i.e., that the *FlowQ*(*FlowSource*(*Flow*)) is greater than *FlowQ*(*FlowDest*(*Flow*)). The second is that *FlowPath* not be blocked. The nature of being blocked depends on the subframe of *Flow*. For instance, a stopper can block liquid flow, but heat can still pass.

Flow has three Consequence FEs: a Quantity whose *QuantityType* is Rate, and two DirectInfluence frames, constraining the *FlowQ* of *FlowSource* and *FlowDest* via *Rate*(*Flow*) with the appropriate signs.

More sophisticated versions of this basic pattern are common in qualitative modeling; e.g., the rate is typically a function of the difference between the driving quantities, and also depends on path properties. Such elaborations do commonly appear in explanatory texts, and consequently the ability of qualitative modeling to support such incremental elaboration, which can be done via additional *Qprop* frames in this case, provides a necessary source of representational flexibility for natural language semantics.

Some empirical evidence

Up to now we have been concerned with expressing the concepts of QP theory in Frame Semantics, showing how they can fit into this larger system and some of their syntactic realizations in English. Here we examine the utility of doing this, in two ways. First, we turn the question around: How much do these ideas contribute to understanding the semantics of texts involving the physical world? Second, can we use these ideas to reconstruct from an explanatory text the physical ideas being communicated? We examine each in turn.

How far can a QP-based frame semantics go in accounting for the semantics of explanatory texts? One way to answer this question is to analyze a corpus of physical explanations, and see what fraction of the sentences require the frames of QP theory (and frames for mental models expressed in QP theory) for their interpretation. We have done this by using four chapters of a book on solar energy, *Sun Up to Sun Down* (Buckley, 1979). We chose this book because it is very clearly written, and we have been using it for a source of examples in other projects, since it uses both diagrams and analogies heavily.³ We chose chapters 2 through 5 because they provide a basic exposition of heat, temperature, and types of heat flow.

Our analysis method was this. Two evaluators familiar with the theory independently scored each sentence. Then

² Note that 'from evaporation' refers to an internal quantity of a process (i.e. the evaporation rate), not to a participant (as in 'from the ocean'). The latter would be marked as a source, not as a constrainer.

³ As additional corpus material, we have selected a college textbook on the weather as well as a children's book on weather, but while these have served as a source of data for our analysis of syntactic realizations, the results in this section are based only on the Buckley text.

they compared their results, discussing divergences until they came to agreement.

We looked at the linguistic realizations of physical processes in the text. Based on the QP frame semantics, we defined nine types of information about processes: the process name (P), information about subclasses of a process (i.e. a specialization) (SC), participants (PA), about conditions: antecedent activations (AA), antecedent ordinal relations (AO), antecedent relations (AR), and finally about consequences: indirect influences (CII), direct influences (CDI), and consequence relations other than influences (CR).⁴ Multiple pieces of information can appear within a single sentence, so we scored number of phrases of particular types in addition to the number of sentences that they occurred in. Sentences can contain multiple types of information, so the same sentence can appear in multiple categories. We also distinguished between information from examples (identified through a preliminary analysis) and general information, since we have hypothesized (Forbus & Gentner, 1997) that common sense physics arises from within-domain analogies involving concrete descriptions. Tables 1 (general information) and 2 (exemplar-specific information) show our results.

Type	P	SC	PA	AA	AO	AR	CR	CDI	CII
#Sentences	10	1	8	15	5	1	9	8	15
#Phrases	11	4	14	16	5	1	18	16	18

Table 1: General statements using QP theory concepts

Type	P	SC	PA	AA	AO	AR	CR	CDI	CII
#Sentences	26	0	28	15	6	5	26	19	14
#Phrases	26	0	74	15	7	5	53	38	17

Table 2: Use of QP theory concepts in examples.

The data shows that the exemplar-specific data contains more than twice the number of processes, about five times the number of participants and a lot more information about the consequences of the mentioned processes. However, the amount of information about the conditions of a process (categories AA, AO, and AR) is nearly the same. As expected, any information about specialization of processes (SC) is only found in the general information.

What kind of coverage does QP theory provide? Of the 216 sentences, 94 of them mention at least one element from the QP frame system proposed here. That means that QP theory can account for roughly 43% of these chapters.

Let us turn to the second question, the reconstruction of a QP domain theory from the frame semantics that one might get from analyzing a text. Again we rely on Chapters 2 through 5 of Buckley (1979). These chapters yield six physical processes: General models of heat flow and volume

flow (e.g., liquid flow), and four subclasses of heat flow (conduction, convection, radiation, and transport). Using this data and the information about the constituents of processes it contains, we attempted to manually reconstruct the models of the underlying physical processes. Figure 1 shows the reconstructed model of the generic heat flow process. One piece of information in Figure 1 marked with a star was not part of any general description of the heat flow process but originated from information about specific examples. It was generalized and included into the generic process model. By combining information from specific examples with general information, reasonable QP theory process descriptions of each were obtained.

These results are very encouraging. The frame semantics based on QP theory provides significant coverage of this corpus. The aspects that are not related to QP theory are not themselves physical laws or behaviors per se, but require frames of the types that would be found in other kinds of texts. Thus these results suggest that the frame semantics we propose using QP theory could play a useful role in a broad system of natural language semantics.

Discussion

This paper argues that qualitative physics, specifically QP theory, can be used as a component in a system of natural language semantics. We outlined how QP theory can be recast in terms of Fillmore's frame semantics, as used in the FrameNet project. The constructs of QP theory can be recast in terms of a collection of frames and subframes, which can be used to describe many causal mental models found in explanatory texts. As the syntactic realizations of these frames are further worked out, we believe that they will be a valuable extension to FrameNet semantics.

In addition to broadening the coverage of FrameNet to include a wide range of continuous phenomena and systems, our extension also grounds these new frames in terms of a well-worked out knowledge representation formalism capable of supporting qualitative reasoning. The compatibility of existing FrameNet motion descriptions with this model, and our analysis of a QP model of flow in frame semantics, lends support to our claim that this recasting of qualitative modeling can productively extend frame semantics for natural language.

The corpus analysis presented suggests that this extension can be useful, since 43% of the material in sample chapters from a typical science book can be captured in terms of them. Moreover, our analysis suggests that these frames could be composed to construct domain theories of a kind already used in qualitative reasoning.

Our results suggest that QP frame semantics can indeed play an important role in natural language semantics for physical texts. More investigation is needed on several questions, including:

- We want to refine our estimates of coverage by analyzing a larger corpus with a broader range of materials. These analyses are impractical by hand, so we are exploring the use of automated tools for subsequent analyses.

⁴ Although the information involved in these categories has varying complexity, e.g., influences and ordinal relations are more complex than the process or participant names, we do not impose any ordering or weighting on these pieces of information.

```

Process HeatFlow

  (I- (heat loc1) flowrate)
  (I+ (heat loc2) flowrate)

```

Figure 1: One QP physical process description reconstructed from the Buckley text. The line marked with "*" was derived via generalization from specific examples.

- We view our work as complementary to that of Narayanan (1999), who is linking FrameNet semantics with sensory-motor schemata. Both will ultimately be needed, and their interplay will be interesting to explore.
- The same QP analysis used for literal language could be used to improve the productive understanding of many metaphors. For example, the FrameNet analysis of heat in the emotional domain has tied to it the lemma *boil* directly. If QP representations for heat, heat flow, and boiling were used instead, one could infer that making someone angry for longer could lead to boiling, and that if someone had "boiled over", starting a heat flow with them as the source, could "cool them off".
- A fascinating set of questions arises from cross-linguistic comparisons. Are these ideas bundled up in the same way in all languages, or are they realized very differently (e.g., Bowerman's (1996) cross-linguistic analysis of spatial prepositions, Talmy's (1985) cross-linguistic analysis of verb semantics, and Imai and Gentner's (1993) analysis of the mass/count distinction)?

Another goal of our analysis is synthesis, i.e., to create a habitable controlled language that can be used in natural language processing systems that communicate with people about the physical world more fluently. Such software could be invaluable in creating new kinds of intelligent software, such as tutoring systems and monitoring systems.

Acknowledgments

We thank Jason Trost for help with the corpus analysis, and Larry Birnbaum and Dedre Gentner for insightful comments on the paper. This work was supported by the Artificial Intelligence program of the Office of Naval Research.

Abstract

The central aims of this experiment were to compare observational and interventional learning of a simple causal chain, and to ascertain whether people represent their interventions in accordance with the normative model proposed by Pearl (2000). In the observation condition people treated putative causes as independent, and systematically selected the wrong model. In the intervention condition performance improved, in particular greater sensitivity was shown to the relevant conditional independencies. However, participants' likelihood judgments approximated the observed frequencies rather than reflecting the appropriate causal model.

Introduction

Our causal knowledge of the world is closely tied to our ability to control or manipulate certain aspects of it. On the one hand, we often learn about cause-effect relations by observing the effects of our own interventions (e.g., running controlled experiments). On the other, we can exploit such knowledge by manipulating the causes appropriate to our desired ends. Further, our causal knowledge allows us to predict or imagine the consequences of our actions, and is thus a prerequisite for deliberative decision-making.

Given the central role that intervention plays in causal reasoning, it has received scant attention in most accounts of human causal learning. In part this is due to the lack of a formal analysis of intervention, and the failure of standard probability theory to distinguish *action* from *observation* (Pearl, 2000). These lacunas appear to be addressed by a body of recent research in AI, which provides a normative analysis of causal inference and a formal means of representing the difference between observation and intervention (e.g., Glymour, 2001; Pearl, 2000).

The formulation of a normative model is at best only a first step towards an understanding of how people acquire and employ causal knowledge. The current experiment aims to gather some preliminary evidence about the difference between observational and

interventional learning, and whether people represent their interventions in the manner suggested by this normative account.

Causal Models

The causal model framework offers a method for representing causal knowledge and formal rules for updating this knowledge in the light of either observation or intervention. Central to this formalism is the use of directed graphs to represent the mechanisms that underpin our causal knowledge of a domain, and the use of probability theory to reflect the uncertain and defeasible nature of this knowledge.

Figure 1: A causal graph

A causal model is made up of a set of nodes, a set of directed links between nodes, and a conditional probability distribution for each node. The nodes correspond to variables relevant to the domain (the pre-selection of which may be non-trivial); these may be binary, or take on a range of values. The directed links between variables correspond to the autonomous mechanisms that are supposed to mediate between these variables, and hence reflect the dependencies between them.

A simple causal graph is depicted in Fig. 1. In this example the model is restricted to three binary variables: *Bronchitis*, *Cough*, and *Insomnia*. There is presumed to be one mechanism that leads from *Bronchitis* to *Cough*, and another that leads from *Cough* to *Insomnia*.

Typically the dependencies between variables are probabilistic – reflecting either the incompleteness of the causal model or genuine noise. This uncertainty is represented by conditional probability distributions for each node (referred to as the *parameterization* of the

graph). Thus in our simple example the strength of dependency between *Bronchitis* and *Cough* is represented by two conditional probabilities – the probability of *Cough* given *Bronchitis*, and the probability of *Cough* given no *Bronchitis*. A high probability for the former would correspond to the belief that *Bronchitis* is very likely to cause *Cough*; a high probability for the latter would correspond to the belief that *Cough* is also very likely to be caused by other variables not represented in our simple model.

Given certain assumptions,¹ the structure of a causal graph will fully capture the probabilistic dependencies amongst all of the represented variables. A fundamental relation here is that of ‘screening off’ or conditional independence. For any three variables *A*, *B*, *C*: *A* and *B* are conditionally independent given *C* if $P(A|B \& C) = P(A|C)$; once you know the value of *C*, learning the value of *B* does not provide additional information about *A*. One causal graph representation that implies screening off is when *C* intercepts all directed paths between *A* and *B*. Thus in the causal graph in Fig.1, the fact that the *Cough* node is in between the nodes for *Bronchitis* and *Insomnia* implies that *Bronchitis* and *Insomnia* are conditionally independent given *Cough*. Once you know the value of *Cough*, learning the value of *Bronchitis* tells you nothing more about the value of *Insomnia*.

By representing conditional independencies in this way, causal graphs provide a powerful tool for organizing knowledge, and for inferring the effects of new observations. As the graphs increase in size, these independence relations can greatly simplify such computations. For example, one could supplement the simple model in Fig.1 with a complex network of nodes and links between *Bronchitis* and *Cough*, but so long as the variable *Cough* still intercepts all links from *Bronchitis* to *Insomnia*, knowledge of *Cough* is all one needs to make inferences about *Insomnia*.

Making inferences given new information

The structure of a causal graph, in combination with the parameterization of its nodes, determines what inferences we can make on the basis of new information. When this information takes the form of an observation, then Bayesian updating tells us how we ought to modify our probabilities. For example, given the causal model in Fig. 1, if we find out that Jim has a cough, we should increase (to some degree, depending on the parameters) both the probability that Jim has *Bronchitis*, and the probability that he has *Insomnia*. However, what if we changed the value of *Cough* by giving him a cough suppressant? Such an action warrants a change in our belief that he has *Insomnia*,

¹ For example, the explicit representation of any variable that affects two or more other variables in the model.

but does not warrant any change in the probability we assign to him having *Bronchitis*.

More generally, the probabilistic inferences we are licensed to draw after observing the value of a variable may not be the same as those after intervening to set that variable to the same value. Bayesian updating, indeed any formal probability model, fails to recognize this. It does not differentiate between *observing* and *acting*. That is, the same conditional probability $P(X|Y)$ is used to represent the probability of *X* given that *Y* is *observed*, and the probability of *X* given that *we do Y*. But these can be quite different, as our example illustrates – the probability of *Bronchitis* given the absence of a cough is distinct from the probability of *Bronchitis* given that we remove the cough.

The Representation of Intervention

One of the innovative features of the causal model framework is that it proposes a normative account for the representation of interventions, and for the inferences that they license. In so doing, it formalizes the difference between observation and intervention.

Pearl (2000) achieves this through the introduction of the ‘do(•)’ operator. In short, this amounts to representing an intervention in terms of a minimal modification of the causal graph. Thus a simple intervention to set a variable to a particular value is represented by the removal of all arrows into that variable, without altering the other directed links in the graph. The effects of the intervention are then computable through Bayesian updating on this ‘mutilated’ graph.

To illustrate using the graph in Fig.1, consider an intervention (e.g., use of a cough suppressant) that sets *Cough* to the value low. This leads to the modified graph in Fig. 2: The directed link from *Bronchitis* to *Cough* is deleted whilst the link from *Cough* to *Insomnia* is left unchanged. In effect the intervention amounts to placing the variable *Cough* under the influence of a new mechanism that sets its value to low.

Figure 2: Causal graph after intervention

This account provides a normative model for the representation of both actual and imagined interventions, and tells us how these interventions will (or would) affect the values of the other variables in the system. In particular it dictates which probabilistic inferences we are entitled to make. Thus the modified graph in Fig. 2 permits us to infer a lower probability of *Insomnia*, but no change in the probability of

Bronchitis. The latter prohibition is reflected in Pearl's terminology by the difference between $P(\text{Bronchitis}|\sim\text{Cough})$ and $P(\text{Bronchitis}|\text{do}(\sim\text{Cough}))$, and captures the basic asymmetry of the cause-effect relation: manipulating a cause can change an effect but not vice-versa.

Learning causal structure

The appropriate representation of intervention is not just critical to predicting the effects of our actions; it is also important for the discovery or learning of causal structure. Causal models can be learned from explicit instruction about how the world works, but we can also learn about causal structure through observation or through intervention. These are not exclusive, but it is useful to distinguish cases in which one is restricted to observational data alone from those in which one also has the opportunity to intervene.

Observational learning

The causal model literature in AI has developed various algorithms for inferring causal structure from observational data, many of which exploit the conditional dependencies encoded in the structure of a causal graph. So far none of these have been proposed as models of actual human discovery, although they do suggest some general principles that are relevant to such enquiries. For example, the establishment of conditional dependencies is a crucial starting point for the construction of a causal graph, so it is important that people are able to make judgments of conditional dependence versus independence. In contrast, the precise parameterization of those dependencies is not always required to discover correct causal structure.

Moreover, the graphical approach clarifies which causal structures can be differentiated on the basis of observational data alone. It establishes equivalence classes of structures ("Markov equivalence") that share conditional dependencies and are thus indistinguishable on the basis of observation alone.² For example, in a model made up of just two nodes, *A* and *B*, ascertaining their probabilistic dependence does not tell us whether *A* causes *B*, or *B* causes *A*.

Even if causal structures are from different Markov equivalence classes, it might be difficult for people to distinguish them on the basis of observational data. Indeed, selecting between certain structures requires careful tracking of observed frequencies and subtle inferences based on what one would expect to see. For example, consider the two possible causal structures depicted in Fig. 3. In order to distinguish these on the

basis of observation alone, one must determine whether or not blurred vision and headache are independent given high wine consumption (conditional independence would only hold if the data were produced by the model on the right). This may require many observations and careful tracking of the relevant relative frequencies.

Figure 3: Two possible causal models

Interventional learning

Another way to learn about causal structure is to actively interact with the system under study and to observe the consequences. This seems to apply to the infant playing with a new toy as much as to the scientist running controlled experiments. Whilst this is often recognized as an important source of causal knowledge, it has received less attention in the human causal learning literature.³

Intuitively, the ability to intervene on a system should facilitate our learning about its causal structure. To take the simplest example, consider two variables that are known to be probabilistically dependent. Assuming no other relevant variables, the direction of this link can be determined by manipulating one of the variables and observing whether or not the other also changes. In a noisy system such learning may still require multiple trials and sensitivity to the observed frequencies. But interventional learning has several advantages over passive observation. Not only can it help to determine the direction of the causal links, it also allows selection of the kind of data to see, and thus to test out critical relations between variables. For example, let us return to the task of distinguishing between the two possible causal models in Fig. 3. One possible intervention is simply to drink a large amount of wine and then keep your eyes closed. If you don't get a headache, you can be reasonably sure that the chain model is the correct one. If the system is rather noisy you may have to repeat this experiment several times,

² One important qualification here is in the case of graphs in which causal links are necessary but not sufficient; that is, for a directed link from *A* to *B*: $1 > P(B|A) > 0$ and $P(B|\sim A) = 0$. Networks built from such links may be distinguishable even though they are Markov equivalent.

³ The dominant approaches to human causal learning (e.g. Cheng, 1997; Dickinson, 2001; Shanks, 1995) concentrate on observational learning.

but it will still lead to greater confidence than making the distinction on the basis of observation alone.

Overview of Experiment

The central aims of this experiment were to compare the observational and interventional learning of a simple causal model, and to ascertain whether people represent their interventions in accordance with the normative model proposed by Pearl (2000). We used a typical observational learning paradigm (e.g. Shanks, 1995), but adapted it to include an interventional learning condition and a model selection task. The learning data were generated from a simple chain model (see Fig. 4).

Learning performance was assessed both through a model selection task and through the sensitivity of people's probability judgments to the appropriate conditional dependencies.

Figure 4: Causal graph used to generate stimuli for both observational and interventional tasks

Method

Participants. Thirty-three undergraduates from Brown University received course credit for their participation.

Materials and procedure. Initial instructions to the participants included an introduction to the notion of a causal model with examples of five candidate models. Each participant then completed both an observational and an interventional learning task. Two cover stories were used, one for each task (task order and scenario were counterbalanced across participants). Participants were asked to imagine that they were space engineers (chemists) running tests on a new rocket (perfume) in order to discover the underlying causal structure. They were told that previous tests had identified two variables as relevant to the success of the test. In the space engineer scenario the relevant variables were *Temperature* (either high or low) and *Pressure* (either high or low), and the outcome variable was whether or not the rocket launched. In the chemist scenario the variables were *Acid level* (either high or low) and *Ester level* (either high or low), and the outcome variable was whether or not the perfume was produced. In the *observation* task participants viewed the results of 50

test trials. On each trial they were shown the values of the two relevant variables, and then clicked on a button to view whether or not the outcome occurred. The learning set was constructed according to a chain model (see Fig. 4) and is shown in Table 1 (order of presentation was randomized for each participant).

Table 1: Frequency of presented instances in Observational Learning condition.

Temperature	Pressure	Rocket Launch	No	Prob
High	High	Yes	16	0.32
High	High	No	4	0.08
High	Low	Yes	0	0
High	Low	No	5	0.1
Low	High	Yes	0	0
Low	High	No	0	0
Low	Low	Yes	0	0
Low	Low	No	25	0.5

Participants then proceeded to a test phase, in which they made various conditional likelihood judgments (e.g., given that *Temperature* is high, and *Pressure* low, what is the likelihood that the rocket launches?) plus a model selection question. This question presented participants with five candidate causal models – two chains, two forks, and a collider (Fig.5 shows one model from each category) – and asked them to select the model that they believed was most likely to have produced the data.

Figure 5: Three models from the selection task

In the learning phase of the intervention task, participants were able to set the value of one of the two relevant variables. They then viewed the resulting values of the outcome variable and the variable they had not intervened on. This learning set was generated from a pseudo-random table constructed in accordance with the same chain model. After running 50 tests they

proceeded to an identical test phase as in the observation task.

Results and discussion

Model Selection. The results for the model selection task are shown in Fig. 6, with the correct chain model designated as chain 2.⁴ There were more correct model selections in the intervention than in the observation condition. However, whilst the correct model was the modal response in the intervention condition, overall responses were not significantly different from the uniform distribution ($\chi^2(4) = 2.91$, *ns.*). By contrast in the observational condition there was an overwhelming bias in favor of the collider ($\chi^2(4) = 40.79$, $p < 0.001$).

Figure 6: Model selection results in interventional and observational conditions (the correct model is chain 2).

Derived judgments of conditional independence. On the model used to generate the learning set (see Fig. 4), *Temperature* was independent of *Rocket launch* conditional on *Pressure*, that is: $P(R|T\&P) = P(R|P)$. Participants' mean ratings for these two likelihoods are shown in Fig. 7. No significant difference obtained between the two likelihoods in the intervention condition, suggesting that participants were sensitive to this conditional independence. This is reinforced by the fact that 19 out of 33 participants judged the two likelihoods equal. This contrasts with the observation condition, in which the mean likelihoods differed

substantially, and only 8 out of 33 participants judged them equal.

Figure 7: Mean conditional likelihood ratings for the outcome variable R (rocket launch).

Compatibility of judgments with the *do* operator.

One way to assess the extent to which participants represent their interventions in line with the *do* operator is to look at their judgments of the likelihood that *Pressure* was high given that *Temperature* was low, $P(P|\sim T)$. Recall that the correct judgment for this likelihood is zero; *Pressure* is never high if *Temperature* is low. However, when participants intervene on the *Pressure* variable and set it to high they temporarily break the link between *Temperature* and *Pressure*. In such cases the value of *Temperature* is equally likely to be high or low (its base rate = 0.5). If participants fail to represent their interventions appropriately, by not 'mentally' removing the link from *Temperature* to *Pressure* when they intervene on *Pressure*, they may erroneously judge that $P(P|\sim T) > 0$. This is because 50% of the time when they set *Pressure* high they will observe *Temperature* as low. In other words, they might fail to mark the distinction between action and observation.

To test out this possibility we compared people's judgments for $P(P|\sim T)$ with the relative frequencies they actually observed; i.e., with the proportion of times they observed both low *Temperature* and high *Pressure* (regardless of whether they intervened on *Temperature* or *Pressure*). As shown in Fig. 8, participants' mean judgments for $P(P|\sim T)$ were very close to the frequencies they observed, and significantly different from the normative value of zero.

⁴ One complication is that the chain model used to generate the data is Markov equivalent to fork 2. However, although not inconsistent with the observational data, this model requires an idiosyncratic parameterization whereby one effect (temperature) occurs more often than its sole cause (pressure). Very few people chose this model in the observation condition.

Figure 8: Mean likelihood ratings and observed relative frequencies in the intervention condition.

This result could indicate a failure by participants to implement the *do* operation when inferring the relation between *Pressure* and *Temperature*. However, there are alternative explanations for this finding. One possibility is that participants interpreted the likelihood question in terms of observational rather than interventional probabilities, and accurately reported the relative frequency with which low *Temperature* and high *Pressure* co-occurred, regardless of whether they believed that low *Temperature* would cause high *Pressure*. This fits with numerous studies showing that people encode the relative frequencies of events automatically, and often use these as a basis for their likelihood judgments (e.g., Hasher & Zacks, 1984).

Second, on Pearl's account the notion of an intervention is only well defined relative to a specific causal model. Thus if people uphold an incorrect model (as the majority of the participants did) they are unlikely to give appropriate estimates for the interventional probabilities. Moreover, even those participants that do select the correct model will have entertained various incorrect ones through the course of learning, and it may be very hard for them to retrospectively revise their prior observations.

Conclusions

This experiment demonstrated a contrast between observational and interventional learning, both with respect to people's model selection and their likelihood judgments. Under observational learning, participants exhibited a strong bias for the collider, despite the fact that the variables they judged to be independent were highly correlated in the data. This suggests that they were engaged in predictive learning of the outcome variable (e.g., *Rocket launch*) on the basis of two indicator cues (e.g., *Temperature* and *Pressure*), effectively treating them as independent causes of the outcome. This resonates with research on associative

learning (e.g., Shanks, 1995), and multiple cue probability learning (e.g., Hammond, 1996), where models that assume the independence of causes fit the human data well. One factor likely to encourage this kind of learning was the manner in which the data were presented (e.g., indicator variables followed by outcome variable).

Interventional learning increased sensitivity to the appropriate conditional independencies and eliminated the bias for the collider, but the effect on model selection was not entirely beneficial. Although the correct chain was the modal choice, the majority of participants still chose the wrong model. Taken together with the observational results this implies that participants might have experienced too few trials to confidently discriminate between the models.

Whatever the precise reasons for sub-optimal performance in these tasks, the experiment shows that the automatic mechanisms that allow us to engage in the predictive learning and encoding of noisy information can sometimes override our discovery of the causal model that generates this information. Nevertheless, the difference we did find between observational and interventional learning encourages us that people are able to make use of the special kind of information afforded by intervention, and that future models of learning need to incorporate methods that represent the effect of action.

Abstract

The study of the conceptual representations that underlie the use of language is a problem motivated from both a cognitive research point of view and that of construing language models for various language processing tasks. In this work, we organized 600 Finnish verbs using the SOM algorithm. Three experiments were conducted using different features to encode the verbs: morphosyntactic properties, individual nouns, and noun categories in the context of the verb. In general, the morphosyntactic properties seem to draw attention to semantic roles, whereas nouns as features seem to highlight clusters formed on grounds of topics in the text.

Introduction

Observation of language use provides indirect evidence of the representations that humans utilize. The study of conceptual representations that underlie the use of language is important for applications such as speech recognition. Due to the redundancy in communication, by studying large amounts of data it may be possible to induce the conceptual, system-internal representations which provide a grounding for meanings of words. Whether this is possible, and if so, how, is an interesting and controversial question.

A central problem in learning a language or in estimating a language model¹ from data is how to generalize from particular observations to new, similar instances. Generalization requires knowledge of similarities between words, concepts and other units of language and thought, i.e., similarity representations.

The hypothesis that the semantic similarity of two words correlates strongly with the similarity of their contexts has been widely discussed in linguistics and psychology (for recent treatments, see Levin, 1993 and Miller & Charles, 1991).

It has been proposed by Gärdenfors that a central part of our conceptual representations are

grounded in various low-dimensional *conceptual spaces*. A conceptual space is defined as a set of quality dimensions with a geometrical structure (Gärdenfors, 2000). Examples of conceptual spaces near our perceptual apparatus are colors and the pitch of sounds. For many higher order concepts a geometric interpretation can be found, as well. For example, comparative relations such as 'longer than' can be represented as a geometric relation between two elementary length spaces. Gärdenfors proposes a subset of concepts called *natural concepts*:

A natural concept is represented as a set of regions in a number of domains together with an assignment of salience weights to the domains and information about how the regions in different domains are correlated.

An inherent and important property of the proposed conceptual spaces is that they provide a meaning representation that is ordered and offers means for representing similarities, often in terms of some continuous-valued underlying qualities. Gärdenfors gives examples of conceptual spaces that humans are likely to have. However, an open research question remains for both brain research and the study of language use: What are the possible conceptual dimensions that humans utilize?

In this work we analyze the use of Finnish² verbs with the following goals in mind: (a) to uncover possible conceptual spaces, i.e., underlying, organizing semantic qualities or properties, (b) to study semantic similarities of verbs in actual language use. In particular, we examine the kinds of semantic or conceptual ordering qualities that appear to affect the distribution of features in the immediate context of a verb, in particular (1) morphosyntactic properties of nearby words, and (2) the nearby nouns and (3) unsupervised categories of nearby nouns. In effect, we rely on the redundancy in communication and assume that certain regularities observed in the distributions of verb contexts will contain significant information about the semantics of the verb as well.

¹For an introduction to statistical language modeling see (Manning & Schütze, 1999). Their applications include speech recognition, machine translation, and dialogue agents that converse with humans in order to perform tasks such as answering questions about train schedules and booking flights.

²Most of the research on language is carried out using English data only, which creates a too narrow or misleading picture of the modeling apparatus underlying language learning and use.

In order to obtain a simultaneous visualization and a clustering of the verbs (and in one experiment, nouns as well), we apply the self-organizing map (SOM) (Kohonen, 1995) algorithm. The visualized ordering of the verbs is studied qualitatively to obtain an understanding of the conceptual dimensions by which the verbs are likely to be organized. Furthermore, the obtained clustering is compared to a kind of 'ground truth', namely a semantic classification of Finnish verbs suggested by Pajunen (2001).

Self-Organizing Map (SOM) algorithm

The SOM (Kohonen, 1982; Kohonen, 1995; Kohonen et al., 1996) is an unsupervised neural network method that is able to arrange complex and high-dimensional data so that similar inputs are, in general, found near each other on the map. The ordered map display can then be utilized to illustrate various properties of the data set in a meaningful manner.

The algorithm automatically places a set of reference vectors—also called model vectors—into the input data space so that the data set is approximated by the model vectors. Each reference vector corresponds to a *map unit* on a two-dimensional regular grid. In effect, the grid and the vectors form a two-dimensional 'elastic net' in the high-dimensional input space: after application of the SOM algorithm, the map follows the data in a nonlinear fashion. The algorithm simultaneously obtains a *clustering* of the data onto the model vectors and a *nonlinear projection* of the input data from the high-dimensional input space onto the two-dimensional ordered map.

Prior work on unsupervised word categorization and projection

It has been shown that distributional information of word contexts can, at least for English, be used to induce syntactic categorization, and to some degree, semantic categorization as well using various methods (cf. e.g., Finch & Chater, 1992; Charniak, 1993; Honkela, 1997; Redington, Chater & Finch, 1998). The SOM has been applied to clustering English word forms based on the word forms in their immediate contexts in (Ritter & Kohonen, 1989; Honkela, 1997). Furthermore, the word categories obtained in such a manner have been used for encoding the meaning of documents e.g., in (Lagus et al., 1996).

Various alternatives to using SOM exist, including other clustering methods such as hierarchical clustering (used e.g. in Redington, M., Chater, N., & Finch, S., 1998; Pereira et al., 1993). Moreover, different metrics or clustering criteria can be applied, such as relative entropy (e.g. in Pereira et al., 1993) or minimum description length (in Li and Abe, 1998). Moreover, projection methods that do not form clusters but only project the data into a lower-dimensional space include a number of nonlinear projection methods under the name multidimensional scaling (MDS), and linear projection

methods such as latent semantic analysis (LSA). Compared to these, a particular property of the SOM is that it simultaneously forms a grouping and a nonlinear projection of the data set.

In constructing the feature vectors for each word, one may look at the occurrence of individual words, or of syntactic word categories, or of morphological or derivational features (e.g. in Light, 1996). The position in which features are examined may be defined in terms of a wide window where more distant occurrences contribute less (e.g. Gallant et al. 1992; Lund and Burgess, 1996), or looking at only specific positions near the word, or according to some grammatical relationship with the word (e.g. Pereira et al., 1993; Schulte im Walde, 2000).

Experiments

We carried out three experiments on organizing and clustering verbs using the SOM algorithm. For the verb encoding, the following types of contextual features were explored: morphosyntactic properties, individual nouns and noun categories.

Corpus and data set

A corpus consisting of 13.6 million words of Finnish newspaper text³ was used in the experiments. The examined set of verbs consisted of the 600 most frequent Finnish verbs, returned to their base forms⁴. Each context of a verb in the corpus was examined. The context was defined as the preceding and the two following words relative to the verb.

Encoding of the verbs

Morphosyntactic properties. In the first experiment, we preferred overtly marked morphosyntactic features. The selected features were 1) case endings (see example (i)), 2) endings of the nominal forms of verbs (see example (ii)), and two closed-class parts of speech, namely 3) adverbs and 4) adpositions (see example (iii)). In addition, the features NUM (for digits), and PUNCT (for punctuation marks) were included since they can be considered as visible features, too.

In Finnish, the primary means for coding various semantic-functional dependencies in a clause is the case-marking system. The case endings are added to stems, as shown in the following example:

- | | | | |
|-----|-----------------------------------|----------|--------------|
| | Lapse-t | ajoi-vat | kaupunki-in. |
| (i) | child | drive | city |
| | N-PL-NOM | | N-SG-ILL |
| | 'The children drove to the city.' | | |

The feature set used also includes two nominal (non-finite) verb forms, namely the 1st and the 3rd infinitive. The infinitives function in a sentence as nouns:

³Corpus by CSC, <http://www.csc.fi/kielipankki/>.

⁴The morphosyntactic analysis of word forms was performed using the Conexor FDG parser for Finnish, ©Conexor Oy and Anu Airola.

- (ii) Halua-n lähte-ä syömä-än.
 want go eat
 V-PRES-SG1 V-INF1 V-INF3-ILL
 'I want to go to eat.'

Location or movement can be coded by using an adposition (iii) instead of case endings. Adpositions include postpositions (PSP) and prepositions (PRE):

- Lapse-t ajoivat kaupunki-a kohti.
 child drive city toward
 (iii) N-SG-PTV PSP
 'The children were driving towards the city.'

The lower-level constituents, e.g., noun phrases, are predominantly head-final, the order being modifier-before-head. Adjectives agree in number and case with the head-noun when they occur as attributes (iv). Due to this redundancy, the function of a dependent noun phrase can be inferred before hearing or seeing the head of the phrase.

- Emmi ajaa punaise-lla auto-lla.
 Emmi drive red car
 (iv) N-PROP V-SG3 A-SG-ADE N-SG-ADE
 'Emmi drives in a red car.'

At the clause level, the basic, or default, word order is subject-verb-object. According to (Hakulinen, Karlsson & Vilkuna, 1980), subjects precede finite verbs in 61% of all sentences in standard written prose. However, as Vilkuna (1989) points out, clause-level word order in Finnish shows great freedom; for example, in a simple sentence consisting of a subject, an object, a verb and one or two adverbials, all permutations are at least grammatically possible.

To sum up, we used a set of 21 mostly non-overlapping morphosyntactic properties, collected from three different textual positions relative to the verb. Each verb was thus encoded using a 63-dimensional feature vector. Averaged over a large number of samples, the value of a dimension in the vector is the conditional probability of a particular morphosyntactic feature in a particular contextual position given that verb.

Individual nouns as features. In the second experiment, instead of morphosyntactic properties individual nouns were used as features. The feature set consisted of the 10,000 most frequent nouns, returned to their base forms.

In order to keep the size of the feature vector reasonable, random projection was applied: Each of the 10,000 nouns was represented as a 500-dimensional vector, where 5 randomly selected positions were set to 1 and the values of the other dimensions were 0. The correlations thus introduced between words are in general negligible: random projection has been shown to roughly preserve distances between vectors, if the dimension of the projected vectors is sufficiently large. A theoretical treatment is presented in (Kaski, 1998); for empirical results on the use

Table 1: Sample noun categories.

Finnish nouns	Translations	Characterization
Matti, Jukka, Riitta, ...		first names of persons
maanantai, tiistai, ...	Monday, Tuesday	week days
kirja, levy, kokoelma, näytelmä, ...	book, record, collection, play	products of art
syy, pakko, tarkoitus, taipumus, ...	reason, obligation, intention, inclination	modalities

of random projection in the representation of documents, see (Kohonen et al, 2000).

As in the previous experiment, each contextual position was encoded as a separate part of the feature vector. The resulting dimensionality of the vector was 1,500.

Noun categories as features. In the third experiment, noun categories were used as features. The categories were obtained by using the SOM algorithm to cluster the set of the 10,000 nouns from the previous experiment. The nouns were clustered based on verbs appearing in the same sentence at a maximum distance of five words. The position of verbs within the window was not taken into account. Verbs occurring at least 20 times in the corpus were considered as features, which yielded a total number of 3,089 verbs. Again, random projection was applied to reduce the dimensionality of the vectors.

A noun map consisting of 160 units was constructed. Each map unit was regarded as a noun category. Some examples of the resulting noun categories are shown in Table 1.

Next, the feature vectors for the 600 verbs were created. The encoding was identical to that of the first experiment except that instead of morphosyntactic properties, noun categories were used as features. The resulting feature vectors were 480-dimensional.

Creation of verb maps

In each of the three experiments, the feature vectors representing our selection of 600 frequent verbs were organized on a map of 140 units using the SOM ToolBox (Vesanto et al., 2000). As a consequence, verbs having similar feature vectors, and hopefully similar semantic representations, can be found close to each other on the map.

Results

The verb maps generated using different features were evaluated in two ways: by comparing to an

Table 2: Quantitative comparison with Pajunen's classification.

Exp. no.	Type of features	Precision
1	Morphosyntactic	35.7%
2	Individual nouns	23.6%
3	Noun categories	27.5%

existing classification, and by exploring the ordering of the verbs on the visualized maps.

Comparison to an existing verb classification

We compared the obtained clustering to Pajunen (2001), which is the most comprehensive semantic classification of Finnish verbs available. The semantic classification Pajunen presents is based both on conceptual classes, that is abstract schemas of states of affairs, and the theory of semantic fields (about field-theory, see e.g. Lyons, 1977). If compared e.g. to Levin's (1993) large-scale classification of English verbs, it can be seen that both Pajunen and Levin rely on the notion of semantic determination, i.e., the assumption that semantics determines syntax. However, while Pajunen explains form in terms of meaning, Levin (1993: 5) assumes that 'verbs that fall into classes according to shared syntactic behavior would be expected to show shared meaning components.'

Only 200 of our 600 verbs are mentioned in Pajunen's classification. These are divided into 54 classes, with 1-13 verbs per class. The comparison was carried out as follows: The set of verbs that formed a class by Pajunen were considered as correct hits for each other. For each of the 200 verbs, the map unit of that verb was examined, and the precision was the number of hits divided by the total number of verbs in that map unit⁵.

For each experiment, the precisions, averaged over the set of 200 verbs are reported in Table 2. For the experiments 2 and 3, in which random projection was used in feature encoding, the results are averages of five runs with different random seeds. A paired t-test showed significant differences for each pair of experiments ($p=0.9997$ between 1 and 2, $p=0.9706$ between 2 and 3, and $p=0.9853$ between 1 and 3). The experiments, ordered by similarity to Pajunen's classification, were: morphosyntactic properties, noun categories, and individual nouns.

Visual inspection of the maps

The map obtained in the first experiment is shown in Figure 1. The organization of the map seems to highlight the importance of cultural, social and emotional aspects in lexical organization. Dimensions

⁵The verb itself was excluded, as well as all the verbs that were not mentioned by Pajunen.

Table 3: Sample verb categories based on noun categories (Experiment 3).

Finnish verbs	Translations	Topic
myydä, ostaa, tuottaa, palkata, työllistää, kattaa, vuokrata	sell, buy, produce, hire, employ, cover, rent	business
nousta, laskea, kasvaa, pudota, vähentyä, kohota, pienentyä, supistua, noutaa, kallistua	rise, decrease, grow, fall, diminish, rise, get smaller, contract, fetch, go up in price	stock rates
kuolla, hukkua, ampua, surmata, ammua, hyökätä, loukkaantua, menehtyä	die, drown, shoot, kill, moo, attack, get hurt, pass away	dying

of social interaction, wielding of power, the will of an individual person, and manipulative behavior between people all occupy rather strong regions on the map.

The maps based on the distribution of individual nouns and noun categories (not shown) seem to be organized more according to a continuum from verbs describing subjective cognitive events, e.g., the states of mind of an individual, to the verbs expressing mostly social actions. There were clear categories that appeared to be clustered together on grounds of a common topic in the text. Some examples are shown in Table 3.

Note that the verb 'to moo' has apparently fallen into the 'dying' category due to an incorrect morphological analysis made by the FDG parser. The verbs *ampua*, 'to shoot', and *ammua*, 'to moo', have many common forms that are homonyms, e.g. *ammun*, 'I shoot' or 'I moo'. In fact, the FDG is reported to make 2-7 % of disambiguation errors for words in general.

Discussion

Based on visually examining the map and the clusters and a quantitative comparison to Pajunen's categories, the results are promising. It is nevertheless possible that some improvement may be achieved by (1) correcting the errors in preprocessing, (2) trying yet different types of features, feature windows, or feature encodings. Moreover, when the purpose is only to obtain individual clusters and not a visualization or projection (as done by the SOM), different clustering methods should be examined as well.

Morphosyntactic properties appear to correspond most closely to the grounds by which Pajunen's classification is formed: both categorizations emphasize

Manipulative actions in human relationships

recommend, favor, love, approach, criticize,
signify, cause, touch, require, intend,
praise, continue, offer, justify, help,
teach, protect, beat up

Start of action, focus on will or intention

must, aim at, be able to, undertake,
be capable of, begin, commit oneself,
comply, prepare, settle for.

Communication, esp. positive emotional information

say, establish, laugh, be glad, think, smile,
laugh briefly, sigh, remind, stress, tell, etc.

Aggressive / destructive use of power

Figure 1: A map of the 600 verbs organized based on the distribution of morphosyntactic properties (non-finite forms of the verb were excluded). Properties of the preceding word and the two following words were considered. The contents of four sample map regions are shown in the insets. Many of the obtained categories correspond to categories defined by Pajunen. However, in Pajunen's classification the verbs in the lower right corner indicating 'destructive use of power' are further divided into two specific categories, namely (1) break verbs (*tuhota* 'destroy', *katkaista* 'break', *hajoittaa* 'break down') and (2) fight verbs (*pysäyttää* 'stop', *kukistaa* 'defeat', *tyrmätä* 'knock out'). Similar categories can be found in (Levin, 1993) for English verbs.

the semantic roles a noun phrase may bear in its clause. This seems reasonable, since in Finnish, the primary means to express semantic roles (e.g. AGENT and PATIENT) is the case system. Even though semantic roles cannot be simply derived from morphosyntactic cases, a strong correlation can still be assumed.

The other feature types, i.e. individual nouns and noun categories, exhibit fairly similar information regarding the verbs. In general, morphosyntactic properties seem to push the categorization towards the direction of linguistic semantics, while categorization based on nouns or noun categories is more a reflection of subject matters communicated through texts.

In some cases, the morphosyntactic map distinguishes verbs based on the *kind* of the patient (upper left corner with human → {human} relationships vs. lower right corner with human → {nation, abstraction} relationships). This result confirmed our expectations, and the understanding that the type

of consequence of the action for the patient is not reflected in the morphological features. On the other hand, the maps based on noun features seem to make distinctions based on both the topic, the consequences for the patient {dying, creation, change of possession, change of state}, and the kind of patient {human, food, artefact}. In this way, the different types of features highlight different relevant aspects of categorizing verbs.

Conclusions

Different feature selections correspond to different assessments of what is important in the categorization of verbs. The categorization most similar to Pajunen's was obtained with morphosyntactic features. In contrast, it appeared that the noun features bring out the similarities between verbs in a richer and more useful manner.

It is interesting to consider whether the ordering qualities observed on the maps could count as quality dimensions of the conceptual spaces suggested by

Gärdenfors. The observed ordering qualities seem to reflect various higher-level cognitive, emotional, or social dimensions. These could be emergent properties of representations on some lower, more basic level. In fact, the emergent properties of one representation level or process are likely to be used as input features of another level or process.

By looking at the maps it seems clear that there are many relevant aspects for categorizing verbs, and any single categorization or ordering is of necessity reduced into considering only some of these. However, to obtain a more accurate representation, instead of a single categorization or projection, one should create several simultaneous categorizations (representations), induced using different kinds of features.

Abstract

Multitasking allows people to cope with the ever changing and complex world that we live in. However, as much as cognitive scientists have learned about the details of human cognition, the question of how people acquire multitasking ability remains a mystery. In this paper, we argue that multitasking can be best understood as a product of skill acquisition. In particular, we describe *production composition*, a computational theory of procedural skill acquisition, which can account for the acquisition of multitasking skill. We explore this idea in this paper as part of our effort to develop a cognitive model of a simulated air-traffic controller Task.

Introduction

Multitasking is a critical ability that allows people to cope with and flourish in the complex world that we live in. However, as much as cognitive scientists have learned about the inner workings of human cognition, our ability to multitask remains a mystery. In this paper, we argue that we can best understand multitasking as a product of *production composition* (Taatgen & Lee, submitted), a computational theory of procedural skill acquisition that has been implemented within in the ACT-R framework (Anderson & Lebiere, 1998). Production composition has been used successfully to account for skill acquisition in a wide variety of domains including language learning (Taatgen & Anderson, submitted) and individual differences in complex skill acquisition (Taatgen, 2001). We believe that it can also be used to account for the acquisition of multitasking skill.

Multitasking

Multitasking is the ability to handle the demands of multiple tasks simultaneously. At the most basic level, this may involve executing multiple perceptual-motor actions at the same time, such as moving your attention to the next lane and turning the steering wheel. At a more complex level, this may involve interleaving the steps of many complex tasks, such as shifting down to a lower gear while navigating a curve and carrying on a conversation.

Important insights into people's ability to multitask come from the dual-task performance literature. One such insight is that while there is some interference between the two tasks that are being performed (with a caveat regarding the modality of stimuli and responses), people can consciously trade off performing one task for the other (Wickens & Gopher, 1977). Another is that people's performances in both tasks depend highly on their skill in the individual tasks (Allport, Antonis, & Reynolds, 1972). That is, being skilled in one task allows a person to perform it and other tasks with negligible impact on the overall performance of both tasks. For example, a skill driver might have little difficulty talking with a friend while driving, whereas a novice driver might find it difficult.

Skill Acquisition

Anderson (1982) proposed a theory of skill acquisition in terms of transitioning from declarative knowledge to procedural knowledge through a process called *knowledge compilation*. Initially, knowledge is in declarative form and is interpreted. Interpreting declarative knowledge is slow and may lead to errors, especially if the relevant knowledge cannot be retrieved when needed or erroneous knowledge is retrieved instead. With practice, declarative knowledge is compiled into procedural knowledge and is fast and free of errors. Newell and Rosenbloom (1981) proposed an alternate theory of skill acquisition called *chunking* that became an important component of the Soar cognitive architecture (Newell, 1990). Within Soar, skill acquisition is a function of combining multiple procedures into a single procedure and converting the current goal context into a more specialized procedure.

Production Composition

Production composition is a theory of skill acquisition that incorporates aspects of both Anderson's and Newell and Rosenbloom's account. It involves compiling declarative knowledge into procedural knowledge and combining multiple procedures into a new procedure. Consider the process of retrieving

information from declarative memory in ACT-R, which is usually done in two steps. In the first step, a production rule¹ issues a request to declarative memory for a certain piece of knowledge, while in the next step another production rule acts on the retrieved knowledge. Production composition eliminates the retrieval process and creates a single production rule out of the two original rules while substituting the retrieval into this new production rule. Through this process, general rules can be specialized into task-specific rules.

Figure 1 graphically illustrates this process. Before production composition takes place, a production rule requests an instruction from declarative memory on what to do next. Declarative memory returns with an instruction that the Enter key should be pressed in the current context of "Land plane 3". In response a production rule issues a motor command to press the Enter key, which initiates the motor system to actually press the Enter key. Production composition eliminates the retrieval from declarative memory and combines both of these production rules into one single rule, producing a task-specific production rule that issues a motor command to push the Enter key once it is in the context of "Land plane 3".

Production composition has been used successfully to model learning in a simulated air traffic controller task (Taatgen & Lee, submitted), inflection of the English past tense (Taatgen & Anderson, submitted) and the German plural (Taatgen, 2001), and strategy development in the balanced-beam task (van Rijn, van Someren & van der Maas, submitted). Perhaps reflecting the utility of production composition, it has been incorporated into the current version of the ACT-R cognitive architecture. In the next section, we discuss how production composition can be used to account for the acquisition of multitasking skill.

Multitasking and Production Composition

In the example given in Figure 1, all steps are executed serially. According to the ACT-R theory, however, each of the different subsystems, Hand, Declarative Memory and Production, as well as the Visual and other sensory-motor systems can work asynchronously and in parallel (Byrne & Anderson, 1998). This is not always possible: sometimes one subsystem must wait for information from another. The goal of multitasking in such cases is to exploit these gaps in processing by slipping in other useful processes. The production composition mechanism is capable of modeling this aspect of multitasking. Figure 2 gives a graphical example of this process, in which two tasks have to be carried out: Task

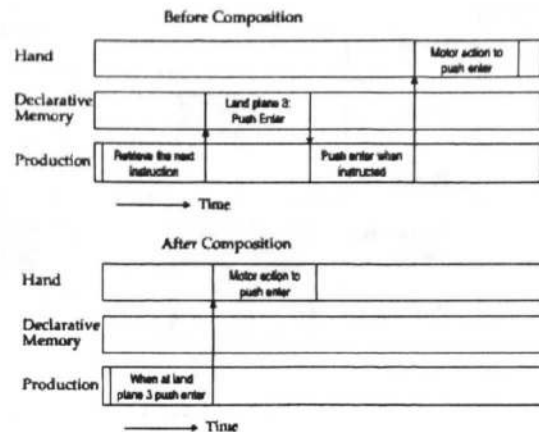

Figure 1: The production composition process.

A to push the Enter key and then check whether a light has gone on, and Task B to say "yes". Obviously these tasks do not make any sense without context, but consider them as part of a larger task, for example in context of the simulated air-traffic controller task that we will discuss later on.

The top left panel of Figure 2 depicts Task A for the novice, comparable to Figure 1. First, a production rule issues a request for the next instruction. Declarative memory produces the instruction to push the Enter key. Next, a production rule issues a motor command to the Hand to do this. Although it takes the motor system some time to execute this command, a production rule immediately fires to retrieve the next instruction.

The retrieved instruction requests the visual system to check the light after the button has been pushed. The production rule that carries out this request has to wait for the instruction and the completion of the previous motor command. Only then can it issue a command to the visual system to check the light. Task B has a similar, although slightly simpler structure: an instruction is retrieved, after which the speech system is instructed to say, "Yes".

If both task A and B rely on declarative instructions, it is impossible to carry them out concurrently because declarative memory is busy almost all of the time. Once production composition has taken care of some of the declarative retrievals, multitasking is possible. Suppose task A has been composed into task-specific production rules but not task B. Now task A is carried out as in the top right panel of Figure 2: a rule issues the motor command, the motor command is carried out, after which a production rule issues the perceptual command. But now there is time left after the first production rule to do something else, for example slip in task B. The bottom left panel shows how this is done. After a rule has fired to initiate the Hand command, a new rule fires

¹ Within ACT-R and other cognitive theories, procedural knowledge is often represented by *production rules* that have the form of "IF-THEN" condition-action rules.

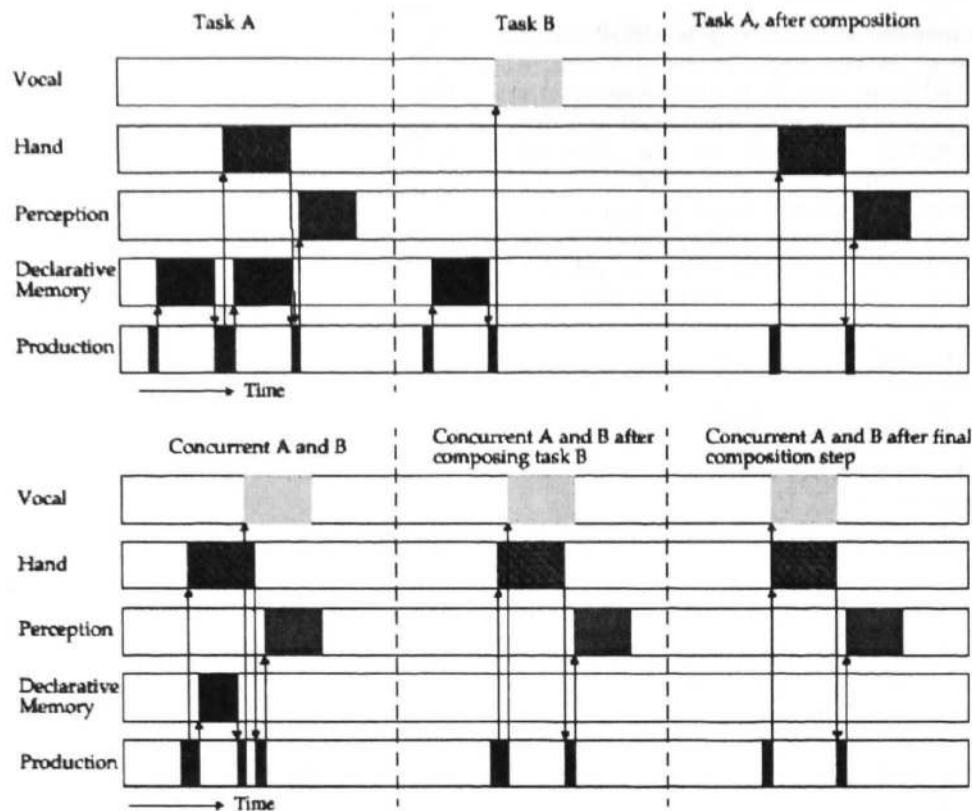

Figure 2: Development of multitasking production rules through production Composition.

to retrieve the instruction for task B. Depending on whether the Hand or retrieval from declarative memory is faster (we chose declarative memory in this case), the Vocal or the Perceptual command is issued. The other follows directly afterwards. The composition process does not stop here, because the retrieval in task B can also be eliminated, producing the situation in the bottom middle panel. Finally, the rule that initiates task A can be combined with the rule that initiates task B, producing the final state of the bottom right panel of Figure 2.

The Task

The task that we use in this paper to explore the concept of multitasking as skill acquisition is the Kanfer-Ackerman Air Traffic Controller (KA-ATC) Task (Ackerman, 1988; Ackerman & Kanfer, 1994). The KA-ATC task is composed of the following elements displayed on the screen: (a) 12 hold positions, (b) 4 runways, (c) information on current score, landing points, penalty points, conditions of the runways, and wind direction and speed, (e) a queue of planes waiting

to enter the hold, and (f) 3 message windows, 1 for notifying of weather changes, 1 for providing feedback on errors, and 1 for displaying of the rules of the task in response to information requests by the participants. The 12 hold positions are divided into 3 levels corresponding to altitude, with hold level 3 being the highest and hold level 1 being the lowest. A typical display of the KA-ATC task is presented in Figure 3.

Six rules govern participant's actions in this task: (1) Planes must land into the wind, (2) Planes can only land from hold level 1, (3) Planes can only move 1 hold level at a time, but to any open position in that level, (4) Ground conditions and wind speed determine the runway length required by different plane types. In particular, 747's always require long runways, DC10's can use short runways only when runways are DRY or WET (i.e. not ICY), and wind speed is less than 40 knots, 727's can use short runways only when the runways are dry or wind speed is 0-20 knots, and PROP's can always use short runways, (5) Planes with less than 3 minutes of fuel remaining must be landed immediately, and (6) Only one plane at a time can occupy a runway.

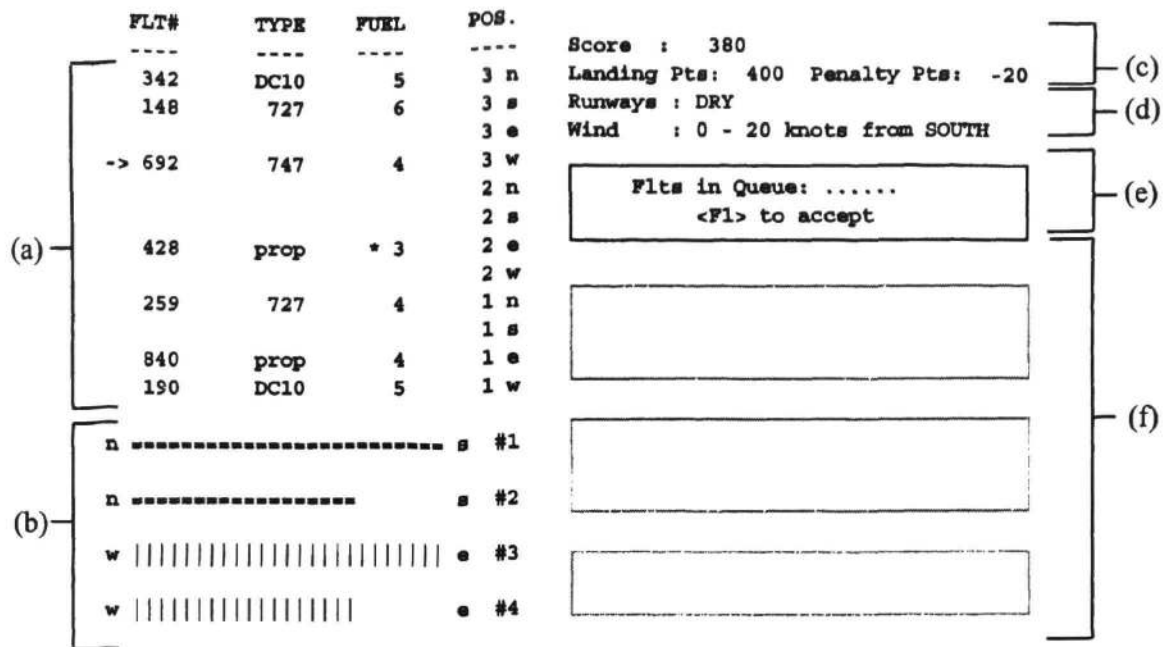

Figure 3: Kanfer-Ackerman ATC Task.

Participants can execute three actions in this task: (a) they can accept a plane from the queue into an open hold-position, (b) they can move a plane between the three hold-levels, and (c) they can land a plane on a runway. They can accomplish these actions by using four keys: the Up-arrow and the Down-arrow keys, ↑ and ↓; the F1 function key, F1; and the Enter key, ↵. They can move the cursor up and down the hold-positions and the runways using the ↑ key and the ↓ key. They can accept a plane from the queue into an open hold-position using the F1 key. And, they can select a plane in the hold, place a selected plane in an open hold-position (either from the queue or from another hold-position), or land a plane on a runway using the ↵ key. In addition, participants can press the number keys 1 - 6 to examine the rules 1 - 6 any time during the task.

Participants are given 50 points for landing a plane, penalized 100 points for crashing a plane, and penalized 10 points for violating one of the six rules. A plane crashes when the fuel-level of a plane falls to 0 minutes. Planes are added to the queue approximately every 7 seconds and it takes 15 seconds for a plane to clear a runway. Once planes enter the hold position from the queue, they have between 4 - 6 minutes of fuel and begin to lose fuel in real time.

In Ackerman (1988), participants performed in the fair-weather condition where the wind speed was fixed to 0 - 20 knots and the runway condition was fixed to

DRY. Under this condition, Rule 4 simplifies to the rule that all planes, except 747s, can land on a short runway.

The Model

Taatgen and Lee (submitted) have developed a model of the initial learning of the task. In this paper we describe a modification of this model to include some aspect of multitasking. The general idea of the model is that the participant in the experiment first encodes the instructions declaratively, forming a (often incomplete) plan on how to do the task. As interpretation of these instructions is slow, initial performance is also slow, resulting in poor performance. But due to production composition, a speed-up is realized that can account for the increase in performance.

The former model consisted of a fairly linear plan to land planes, to decide between the tasks to land planes, to move planes between hold levels and to get new planes from the queue. The model does not allow for much concurrency because of the linear structure of the plan that persists even after proceduralization. In order to test the new approach, we took out one aspect of the plan to land a plane, namely the checking of the wind direction. Wind direction has to be checked to see which of the runways can be used at the moment, and as it periodically changes, it has to be rechecked occasionally. In the original model, the wind was checked as one of the first steps in the landing procedure. We took this checking step out of the main plan, and made an alternative plan to check for the wind

Figure 4: Number of planes landed.

at moments of "slack time", for example when the arrow is moved to a plane or a runway. These arrow movements take multiple key-presses, allowing for some time for the model take a quick peek at the wind direction. This checking procedure will only succeed after the relevant steps have been proceduralized themselves, similar to the example in Figure 2.

The main question to be answered now is whether this change from a linear to a more parallel model improves the fit with the data. An interesting dependent measure in this respect is the time it takes for the participant (or model) to notice a change in wind direction. Although this cannot be measured directly (at least not in human participants), a measure (also used by Ackerman) is the elapsed time between a change in wind direction and the first landing of a plane on a runway in the new direction.

We compare the model predictions with data from Study 2 in the ONR data set (Ackerman & Kanfer, 1994), as reported in Ackerman (1988). The data from Study 2 were from 65 college undergraduates who completed 27 trials of the KA-ATC task with each trial lasting 10 minutes. For our model comparisons we only use trials 1 through 10, all in the fair-weather condition.

Figure 4 shows the overall score in terms of the number of planes landed in each 10-minute trial. Both the scores for the original "linear model" are shown (from Taatgen & Lee, submitted), and the predictions by the new model. Although the new model is more accurate than the old, linear model, the difference is slight. A larger difference can be seen in the time to notice a change in wind direction, the measure closely tied to the change in the model. Figure 5 shows the results. Although the linear model also predicts an improvement in this reaction time, because all processing is faster due to proceduralization, the new model matches the data much more closely especially in the first three trials where the model still has trouble interleaving checking the wind with other behavior.

Figure 5: The elapsed time between a change in the wind direction and the first plane landed.

The current model is not a full implementation of the principle of multitasking within a complex task like the KA-ATC. It just demonstrates one aspect of in the act of checking the wind direction. Fortunately this aspect can be verified empirically. The current model is not yet capable of explaining improvements in performance after trial 10, where human participants still gradually improve but the model does not. This can only be explained within the ACT-R theory by a more efficient schedule of perceptual, cognitive and motor processes (Lee & Anderson, 2000).

Discussion

Multitasking and Planning

It is worthwhile in our discussion to see how multitasking and production composition might be related to other areas of human behavior. Especially relevant is the area of planning that researchers in Artificial Intelligence have looked at closely. The mechanism of production composition is an automated process that is below a person's conscious control that automatically generates new procedural knowledge that are then tuned in their utility with use.

Planning, on the other hand, is largely seen as a deliberative and conscious process. In the context of multitasking, one can clearly imagine people reasoning about the structure of the multiple tasks that they must engage in, and explicitly devising a "plan" to interleave the tasks. This can happen at a larger time scale, such as when attempting to cook several dishes at the same time for a 7-course meal, or at a smaller time scale, such as trying to press the clutch and change the gear when learning to drive a car with a manual transmission.

From our perspective, planning and any other weak-method problem solving is completely consistent with production composition. Weak-methods, such as using instructions, examples, and planning, are all an aspect

of the declarative problem solving process that generates sequential actions that can be exploited by production composition to develop more efficient (i.e. multitasking) procedures.

We believe production composition can provide a resolution to the debate in the AI community between traditional planning versus reactive planning (c.f. Russell and Norvig, 1995). Traditional planning posits that agents reason over situations and actions in order to formulate a plan before taking the requisite actions. Reactive planning on the other hand posits that agents simply find the most applicable action in the current situation and executes them. Within ACT-R cognitive architecture, one can view weak-method problem solving as a mechanism for traditional planning and production composition as a mechanism for reactive planning. Weak methods generate sequential actions that are then used by production composition to generate reactive production rules. This makes perfect sense from the perspective of studying human behavior, since people display both types of planning.

Is Multitasking a Mystery?

Some may wonder, "Why is multitasking a mystery? Isn't it a well understood phenomenon?" Our response is that while the fact that people are able to multitask is well understood, it is less clear how multitasking skill is learned. In particular, most of the current models of multitasking, with very few exceptions, include explicit control structures to switch between multiple tasks. However, the question still remains as to *how* these control structures came into being. We have argued in this paper that multitasking is a product of production composition and is able to learn new control knowledge for performing multiple tasks.

Conclusion

The learning in the KA-ATC task can be conceptualized as retrieving instructions from memory and executing them (Taatgen & Lee, submitted). The two steps are then compiled by production composition into a single production rule. One result of production composition in the KA-ATC task is the acquisition of a keystroke-level task (c.f. Lee & Anderson, 2001). However, another result of production composition is the combining of two (or more) learned keystroke-level production rules into a single rule. This second result, we argue, reflects the acquisition of multitasking skill.

Using Cognitive Decision Models to Prioritize E-mails

Michael D. Lee, Lama H. Chandrasena and Daniel J. Navarro
{michael.lee,lama,daniel.navarro}@psychology.adelaide.edu.au
Department of Psychology, University of Adelaide
South Australia, 5005, AUSTRALIA

Abstract

E-mail prioritization involves placing all of the 'useful' or 'good' unread e-mails at the top of the inbox, and all of the bad ones at the bottom. We use two cognitive decision models—a rational model, which considers all of the available information, and a fast and frugal model that uses one reason decision making—to prioritize e-mails. Experimental results, using real data obtained by unobtrusively logging e-mail user behavior, show that the fast and frugal model is just as effective as the rational model. The results also show that a Bayesian approach to learning is superior to the standard frequentist approach, because it balances the competing demands of exploration and exploitation in finding good e-mails. We use the results to draw some applied conclusions about the development of an e-mail prioritization system, and note some theoretical implications of the results for the cognitive modeling of human decision making in general.

Introduction

Anybody who has returned from holidays to be confronted with 600 unread e-mails appreciates the need for prioritization. Ideally, we would like an unread inbox to rank the e-mails, putting those that are the most 'important', 'urgent', 'useful' or 'good' at the top, and those that are less important at the bottom.

While machine learning methods have been applied to the problem of e-mail prioritization (e.g., Macskassy, Dayanik, & Hirsh 1999; Mehran, Dumais, Heckerman, & Horvitz 1998), it has typically not been treated as a cognitive modeling problem. Clearly, however, prioritizing requires an ability to predict whether or not a user is likely to evaluate a message as a good message, and so requires an effective model of human decision making to be successful.

Using cognitive models for prioritization does not only promise to provide an answer to an applied problem, but also has theoretical benefits for the more general study of human decision making processes. This is because, in the form of real-world e-mails, it deals with a richly structured stimulus domain. There are, of course advantages in studying decision making with artificial stimuli, as is often done in the categorization and classification literature (e.g., Shepard, Hovland,

& Jenkins 1961), because of the experimental control that is achievable. A central argument of ecological approaches (e.g., Simon 1956; Gigerenzer & Todd 1999), however, is that it is also important to consider the role of non-arbitrary stimulus environments in supporting (or confounding) human decision making.

In this paper, we develop and evaluate two cognitive models for prioritization. One is a 'rational' model, that performs exhaustive calculations, while the other is a 'fast and frugal' model, that requires only limited time by making assumptions about the nature of its environment. In the next section, we describe how e-mails are represented by these models, and how information about them is learned. We then describe the two models in detail, before presenting the results of an experiment in which both are evaluated on real-world data. Finally, we draw some conclusions regarding the theoretical implications of the results for understanding human decision making, and the applied implications for building an e-mail prioritization system.

E-mail Representation and Learning

Cues and Cue Validities

We follow previous research in assuming e-mails are represented in terms of a set of binary features, which we call cues. These cues may relate to the content of the e-mail, such as a keyword in the message text, or metadata associated with the e-mail, such as the name of the sender. In this way, each e-mail may be defined by the set of cues that it contains.

Following Gigerenzer and Todd (1999), we associate a cue validity with each cue, which measures the probability that an e-mail will be regarded as good, given that it has the cue. Formally, this means that the validity, v_i of the i -th cue, c_i is defined as $v_i \equiv p(G | c_i)$, where G denotes good. Notice that, because each e-mail is assumed to be either good or bad, $1 - v_i$ gives the $p(B | c_i)$, the probability that an e-mail will be bad when it has the i -th cue.

Learning Cue Validities

Where the cues constitute the representational component of our decision making models, the way in

which the validities are specified constitute the learning processes, in the sense that different validities apply in different environments, and are formed on the basis of information observed in those environments. We consider two methods for learning cue validities, arising from the alternative frequentist and Bayesian statistical approaches. In both cases, we assume that (in ways described later) every e-mail that has previously been processed by a user has been classed as a good e-mail or a bad e-mail. This means that the raw data for the i -th cue take the form of a count g_i , giving the number of good e-mails with the cue, and a count b_i , giving the number of bad e-mails with the cue.

Under the frequentist approach, the validity of a cue is estimated simply as the proportion of good e-mails with the cue:

$$\hat{v}_i = g_i / (g_i + b_i + \epsilon),$$

where ϵ is a small positive number that ensures cues have a defined validity of zero before they have been observed in any e-mail (i.e., the case $g_i = b_i = 0$).

Under the Bayesian approach, prior beliefs regarding the validity of the i -th cue are modified using the data provided by the counts g_i and b_i . As a cue becomes associated with more good e-mails, higher values for its validity become more likely. Conversely, as a cue becomes associated with more bad e-mails, lower values for its validity become more likely. Bayes' theorem describes the way in which the prior beliefs are modified by data to give a probability distribution over the range $[0, 1]$ of possible validities. Defining the validity of a cue as the mean of this distribution, and assuming a uniform prior, gives the result (see Gelman, Carlin, Stern, & Rubin 1995, p. 31):

$$\hat{v}_i = E[p(v_i | g_i, b_i)] = \frac{g_i + 1}{g_i + b_i + 2}.$$

As more e-mails with the i -th cue are processed the counts g_i and b_i increase, and the frequentist and Bayesian approaches converge towards the same value. When few data are available, however, we later show that the Bayesian approach has advantages for prioritization.

Decision Models for Prioritization

The 'Rational' Approach

Under the rational approach to decision making used here, the evidence provided by every cue associated with an e-mail is integrated to give an estimate of the overall log odds that the e-mail is good, as opposed to bad. Assuming that the evidence provided by each cue is independent, and that the prior probabilities of an e-mail being good or bad are equal, then Bayes' theorem gives:

$$\ln \frac{p(G | c_1, \dots, c_n)}{p(B | c_1, \dots, c_n)} = \sum_{i=1}^n \ln \frac{p(c_i | G)}{p(c_i | B)}.$$

The required evidence ratios $p(c_i | G) / p(c_i | B)$ can be estimated from the data in the same way as cue validities, or (with some manipulation) written in terms of the validities themselves. The rational approach has the attraction of considering all of the data, in the sense that it considers the evidence provided by every cue associated with every stimulus. For this reason, it is often considered a normative account of decision making, and has been used extensively (in one form or another) to model human decision making. As an (arbitrary) example, consider Kruschke's (1992) well known ALCOVE model, which uses a weighted sum of the evidence provided by each dimension of a stimulus in deciding whether or not that stimulus belongs to a category. The rational approach is also widely used in machine learning, and has been applied in previous research (Macskassy *et al.* 1999; Mehran *et al.* 1998) on prioritizing e-mails.

The 'Fast and Frugal' Approach

In developing their 'fast and frugal' approach to modeling human decision making, however, Gigerenzer and Todd (1999) challenge the rational approach. They argue that because human decision making processes evolved in a competitive environment, they need to be fast, and because they evolved in a changeable environment, they need to have the robustness that comes from simplicity. To meet these challenges, the fast and frugal approach adopts Simon's (1982) notion of 'bounded rationality', and models human decision making using simple algorithms that rely on an assumed structure in the stimulus environment to function effectively.

For example, in an environment where the validity of one stimulus cue is highly predictive of the validities of the remaining cues, and the examination of additional cues is an effortful process, it is sensible to consider only the first cue. Similarly, in an environment of diminishing returns, where the examination of each successive cue provides less information than previous cues, it makes sense to base decisions on a small number of cues. Gigerenzer and Todd (1999) show that many real-world stimulus domains have these sorts of structures, and develop a number of cognitive models—including the 'Take the Best' model of forced choice, the 'QuickEst' model of value estimation, and the 'Categorization by Elimination' model of categorization—that make inferences by assuming environmental regularities.

Unfortunately, none of these models is directly applicable to the problem of e-mail prioritization, and so

we developed a new model using the basic 'fast and frugal' modeling approach. Gigerenzer and Todd (1999) argue that their models of human decision making are based on simple mechanisms that answer three fundamental questions:

- How should a stimulus environment be searched for information?
- When should this search for information be terminated?
- Once the search has been terminated, what decision should be made given the available information?

In the context of finding good unread e-mails, as required for prioritization, it is not difficult to provide answers to these questions:

- Unread e-mails should be searched in terms of cues, looking for e-mails with high validity cues.
- The search should be terminated as soon as at a candidate good e-mail has been identified. Since users process e-mails serially, there is no benefit in seeking to sort the unread e-mails, beyond attempting to ensure that at any time the top-most e-mail is the one most likely to be good.
- The best available e-mail should be placed at the top of the inbox, as the next one to be read by the user.

These answers suggest a simple fast and frugal decision model for prioritization. The cues are ordered in terms of their estimated validity and, starting with the highest validity, a search is made for an unread e-mail that has this cue. If this search is successful, the process terminates without considering any further cues. If no e-mail is found, the search continues using the next highest validity cue, and this process is repeated until an e-mail is found. This model is closely related to Take the Best, and belongs to the class of what Gigerenzer and Todd (1999) term 'one reason decision making' models. Only one reason, in the form of the presence of a high validity cue, is all that is required to find the next e-mail for presentation.

Experiment

Data Collection

We developed a macro for the Microsoft Outlook e-mail application that unobtrusively logged the behavior of one user for a period of 76 consecutive days. This logging involved recording the actions made by the user in reading, responding to, and organizing the e-mails in their inbox. Every time the user replied to, forwarded, saved, moved or deleted an e-mail in their inbox, an entry in a log file was made. Often, a particular e-mail was subjected to several processing actions

Table 1: The logged e-mail properties used to generate cues, together with a sample cue.

Property	Sample Cue
Attachments	"AttachmentCount=2"
CC list	"CC=mark@adelaide.edu.au"
Flag status	"FlagStatus=0"
Importance	"Importance=1"
Sender's e-mail	"SendersEmail=jdl@mbox.com"
Sender's name	"SendersName=John Lee"
Subject keyword	"Subject=upgrade"
Addressee list	"To=Ben Stamley"

over time, such as being forwarded, and then deleted. We used an operational definition of what makes an e-mail a good or bad one, based on these processing sequences, to enable each e-mail to be labeled as either good or bad. If an e-mail was ever printed, forwarded, replied to, copied to another folder, or saved, it was regarded as a good e-mail. Otherwise, when the e-mail was only deleted, it was regarded as bad. Of course, this sort of operational definition is not unproblematic, but we believe it represents a reasonable first-order approximation for identifying those e-mails that are more 'important', 'useful' or 'urgent'.

The properties of the e-mails being manipulated were also recorded, providing the subject text of the e-mail (for ethical reasons no message content was recorded), as well as metadata identifying the sender of the e-mail, whether it had an attachment, and so on. Those properties taking discrete values were used to generate the cues for representing e-mails by pairing the property with each possible value. Table 1 details the eight properties used in this way, together with an example of a cue for each. The only pre-processing used in generating these cues was to remove common English words from the subject text using a 'stopword' list. The final data set contained 886 e-mails, 362 of which were good, defined in terms of 3,112 binary cues.

Effectiveness of Prioritization

Both the rational and the fast and frugal models were applied to the e-mail data, using the Bayesian learning approach. Each day's e-mails were prioritized in sequence, to simulate the effect that prioritization would have if it were implemented on-line. Figure 1 summarizes the results of 10 independent applications of each method using an effort-reward graph. The performance curves relate hypothetical levels of 'effort', which describe the proportion of available e-mails processed by the user, to the resultant level of reward, as measured by the proportion of available good e-mails that are found. Mean performance levels are shown by the curve, with best- and worse-case perfor-

Figure 1: Effort-reward performance of the rational and 'fast and frugal' decision models.

mance, arising from the stochastic process of breaking ties, indicated by error bars (where large enough to be visible).

Without prioritization, good e-mails are evenly distributed according to their base-rate of occurrence, which corresponds to the diagonal line in Figure 1. The best- and worst-case possible effort-reward performance of prioritization are shown by the dotted lines, which correspond, respectively, to the cases where all good e-mails are presented first, and where all bad e-mails are presented first. Figure 1 shows that the rational and the fast and frugal model perform very similarly. They are close to optimal for the first 10-20% of good e-mails, but then perform less impressively, although they continue to provide a significant advantage over non-prioritized presentation. Reading the first 50% of e-mails, for example, results in finding approximately 75-80% of the good e-mails available.

Figure 1 suggests two important conclusions. Firstly, it shows that prioritization is effective, which suggests that human decisions in processing the e-mails have some level of systematic relationship with the various cues by which the e-mails are represented. Second, the fast and frugal approach is approximately as effective as the rational approach, which suggests that the human decision making process can be understood in terms of the identification of key features of the e-mails, rather than the exhaustive integration of all of their properties.

Figure 2: Effort-reward performance of the 'fast and frugal' model using Bayesian and frequentist learning.

Bayesian and Frequentist Learning

An important theoretical problem for prioritization relates to the balance between exploitation and exploration processes. In the context of e-mail prioritization, exploitation involves using cues that are known to have some validity to find good e-mails, while exploration involves learning more about cues for which little or nothing is known, in the hope of find new sources of good e-mails. Prioritization algorithms are of limited use if they achieve their results by exploitation at the expense of exploration, particularly in dynamically changing environments. For this reason, there has been some considerable effort in the machine learning literature (see Sutton and Barto 1998) to balance the competing demands of exploitation and exploration, usually by introducing some stochastic element into the search process.

As it turns out, the Bayesian approach to learning validities addresses this problem. Figure 2 shows the effort-reward performance of 10 runs of the fast and frugal model using both the Bayesian and the frequentist approaches. To assist in the exposition of our subsequent analyses, only a limited set of cues, consisting of all of those generated from the easily understood 'Senders Name' field were used. As Figure 2 shows, the Bayesian approach performs better, particularly for effort levels greater than about 0.5.

The reason for the superiority of the Bayesian validity estimate can be demonstrated through a concrete example. On day 43, a (small) total of five e-

Table 2: Sender cues, good (G) and bad (B) counts, and estimated Bayesian and frequentist validities for day 43.

Sender's Name	G	B	Bayes	Freq.
ABC News Online	1	140	0.01	0.01
Scott Brown	1	0	0.67	1.00
Tapes Subliminales	0	0	0.50	0.00
Virtual Florist	0	1	0.33	0.00
W. Paul Malcolm	0	0	0.50	0.00

mails required prioritization, coming from five different senders. Of these senders, three had previously sent e-mails: "Scott Brown" had sent one good e-mail, "Virtual Florist" had sent one bad e-mail, and "ABC News Online" had sent 141 e-mails, only one of which had ever been good. These patterns of good and bad counts, together with their Bayesian and frequentist cue validity estimates, are shown in Table 2.

Under the frequentist approach, the "Scott Brown" e-mail will be presented first, because it has been associated with the highest proportion of good e-mails. The next e-mail presented will be the "ABC News Online" e-mail, because it has the next highest estimated validity, by virtue of being the only other sender ever to provide a good e-mail. The remaining two unknown senders have estimated validities of zero, and so their e-mails will be presented in random order. As it happens, one of these e-mails, from the new sender "W. Paul Malcolm" is a good one, and so prioritization will be ineffective. Fundamentally, this is because frequentist validity estimation favors the exploitation of sources with very limited returns over the exploration of unknown sources.

Using the Bayesian approach, the "Scott Brown" e-mail will again be presented first, because it has the highest estimated validity. However, "Virtual Florist" and (especially) "ABC News Online" e-mails will not be presented until after those from the senders about whom nothing is known, because their validities are below the 0.5 prior. In this way, the potential new sources of good e-mails will be explored before those that are known to have limited returns are exploited. Notice also that the "Virtual Florist" e-mail will be presented before the "ABC News Online" e-mail, because less data are available for estimating the validity of the former, and so it has more scope to achieve a higher estimate as more observations are made (i.e., it is more worthy of further exploration). Finally, we note that the situation with many 'spam' e-mails is naturally handled within the Bayesian approach by changing the prior on good e-mails.

Figure 3: The relationship between the maximum cue validity for an e-mail, and its mean cue validity.

The Structure of the Environment

An analysis of the e-mail stimulus domain explains why the fast and frugal approach performs similarly to the rational approach. Figure 3 shows the relationship between the mean estimated validity of the cues associated with each message (using Bayesian learning), and the maximum estimated validity. There is a positive correlation of $r = 0.80$ between these measures, indicating that the maximum cue validity, as used by the fast and frugal method, is highly predictive of the validities of the remaining cues considered by the rational method. This environmental regularity is the reason for the success of the fast and frugal model: By finding the unread e-mail with the greatest cue validity, it does not need to consider further cues, because their validities are largely already determined by the maximum value.

Future Work

The outstanding problem relates to adaptation. If the characteristics of the external e-mail environment change (e.g., people send different types of e-mails), or the user changes the way they regard e-mails as good or bad, prioritization needs to reflect the new situation. The learning processes used in our study will be slow to adapt to these sorts of changes, as demonstrated for the Bayesian approach by the pattern of change of the five cues shown in Figure 4. Validities for the "To=Mike Lee" and "Subject=newmail" cues are learned effectively, because

Figure 4: The pattern of change over all processing days for five cues, using Bayesian learning.

they are consistently evaluated by the user. The "To=fairycake85@hotmail.com" cue, however, is evaluated as good in the first two weeks, but its change to a bad cue is learned slowly. Meanwhile, the cues "Subject=swinburne" and "To=doug.vickers" have similar estimated validities at day 76, yet there are grounds to be more confident about the accuracy of the latter, since it is based on a significant volume of recent data, while the former has not been seen since about day 22.

The ability to adapt requires that memory processes be introduced into the cognitive decision models. By replacing old information in the counts g_i and b_i with new information, giving greater weight to new information, or forcing information to decay over time, validity estimates will be based on data that reflects the current state of affairs. A variety of memory mechanisms have been developed for simple psychological decision models (e.g., Pietsch & Vickers 1997), and their detailed empirical evaluation is a priority for future research. The other necessary area of future research is to extend our evaluation to a larger number of users.

Conclusion

We argued in the Introduction that using cognitive decision models to prioritize e-mails provided a way to address an applied problem, and also advance our theoretical understanding of human decision making. We conclude by suggesting some implications of our results on both the applied and theoretical fronts.

In terms of developing an e-mail prioritization application, the fast and frugal model has significant potential. The data required to drive the algorithm, in the form of user evaluations of good and bad e-mails, is done entirely unobtrusively, does not require any addi-

tional user effort, and provides a continual on-line data source that should allow for adaptation. The balance between exploration and exploitation is handled naturally by the Bayesian approach to validity estimation, and the fast and frugal algorithm scales well to large problems. Only one e-mail with one cue needs to be found at each stage of prioritization, as compared with the rational approach, which examines every cue of every e-mail at every stage.

Theoretically, our results suggest that human decision making in processing e-mails can be understood in terms of a one reason decision making process that is tuned to regularities in its environment, and so supports Gigerenzer and Todd's (1999) fast and frugal approach to cognitive modeling. The Bayesian approach to validity estimation also provides a theoretical tool for any learning or decision making situation where exploration must be balanced with exploitation, and could be used in other cognitive decision models.

Abstract

We present the results of a study examining the effects of category learning on the performance of five year-old children and adults on similarity judgment and same-different tasks. Participants in the learning condition learned to distinguish two kinds of invented alien stimuli by hearing an interactive story over the course of two days, at the end of which they performed three tasks. A comparison of their performance with control participants revealed a marked expansion effect in both children and adults, with learning groups judging between-category pairs to be more different than control groups did. There was no compression effect (within-category pairs were not judged as more similar by learning than control groups). We hypothesize that expansion occurred because distinguishing pairs of stimuli was difficult, as indicated by a high error rate on the same-different task for both child and adult participants.

Introduction

Nearly a decade of research now suggests that the space of similarities within which we locate objects undergoes a systematic change in metric structure in the course of category learning (e.g., Beale and Keil, 1995; Goldstone, 1994a; Goldstone, Lipka, and Shiffrin, 2001; Livingston, Andrews, and Harnad, 1998). This result contrasts sharply with the view of similarity taken for granted in classical descriptions of the category learning, where it is assumed that the metric of psychological similarity is fixed, with the result that the locations of objects within that space, and thus their relationships to one another, are entirely determined by their perceptual properties (e.g.,

Bruner, Goodnow, and Austin, 1956; Hutchinson and Lockhead, 1977). The more recent work suggests that the process of category learning itself may actually alter the similarity space and thus the representational structure of our categories.

Two different kinds of changes to psychological similarity space have now been documented in the literature. *Compression* occurs when one region of the n-dimensional space of similarities changes such that items falling within that region come to have more nearly equivalent encodings than they did prior to category learning. This pattern has been observed by Livingston, et al. (1998), and Kurtz (1996), for example, and manifests as (1) an increase, following category learning, in similarity ratings among items drawn from the same category as compared with items drawn from different categories, or, (2) as greater confusability among items drawn from the same category than among those drawn from different categories. In neural network simulations, the change has been measured directly as an increased similarity in activation patterns on hidden units in a simple feedforward network (Harnad, Hanson, and Lubin, 1995).

The other pattern of change in similarity space following category learning, called *expansion*, occurs when a region of the space of similarities changes such that items falling within that region are judged to be more different after category learning than prior to it, or are less confusable in a same-different task. This pattern has been extensively documented by Goldstone (1994a; 1994b; 1996; see also Goldstone, et al. 2001). In neural network simulations, the change has been

measured directly as an a greater *dissimilarity* in activation patterns on hidden units in a feedforward network (Harnad, et al. 1995; Tijsseling and Harnad, 1997).

In theory, both kinds of changes could occur in the course of category learning, but in general only one pattern is typically observed for a given set of stimuli. Research is currently ongoing to establish the conditions under which one observes compression versus expansion. One hypothesis under active investigation is that expansion is observed in those cases where the discrimination among exemplars in the training set is perceptually difficult, which results in discrimination learning. Compression, on the other hand, occurs when no difficult perceptual discrimination is required. What is important to note, regardless of the ultimate fate of this hypothesis, is that either compression or expansion is sufficient to produce the effect necessary for the psychological distinctiveness that characterizes concepts: a set of similarity relationships that sets the members of the category apart from non-members by its *relatively* greater degree of intra-category similarity (or, alternatively, inter-category dissimilarity).

It has been suggested by many of the researchers who have studied compression-expansion effects that the process may be so fundamental to category learning that it constitutes a basic mechanism by which abstract and universal representations (concepts) are formed (Dampier and Harnad, 2000; Goldstone, 1996; in press; Livingston, et al, 1998). If this contention is correct, then evidence for the operation of this process should be found among young children as well as in adults. To count as truly fundamental to the process by which perceptual categories are built, it should not turn out that compression-expansion effects reflect a strategy acquired late in life or taking a long time to develop. Indeed, it does not appear that there is anything consciously strategic about the process at all; it seems to reflect the operation of an automatic recalibration of psychological similarity space in response to the discovery, during category learning, that a set of items needs to be partitioned in a consistent way. Nevertheless, evidence that this process operates in young children as well as in adults would strengthen the claim that it constitutes a basic mechanism of category learning.

Certainly there is little doubt that children and young infants can learn to make category distinctions, at least among perceptual categories

of the kind at issue here (e.g., Quinn, Slater, Brown, and Hayes, 2001). There is also a growing, if still controversial, body of literature concerning the ability of young children to make use of information about function (e.g., Rakison and Cohen, 1999) or internal, inferred features (Gutheil, Vera, and Keil, 1998) when learning new categories or assigning novel objects to existing ones. There seem to be many similarities between the processes of concept formation in children and adults. To date, however, there has been no successful demonstration that children's category learning is characterized by compression-expansion effects (but see Katz, 1963 for suggestive findings).

The major purpose of the research reported here is to test the hypothesis that the category learning of children will show patterns of compression and/or expansion similar to those already observed among adults. In addition, the present study presents an opportunity to compare performance on similarity judgments with performance (errors and response times) on a same-different discrimination task. The similarity task may be more sensitive to the effects of category learning than the same-different task, but its conceptual complexity makes it difficult to use with children younger than five. Evidence that the same-different task can capture the effects of category learning would clear the way for future work with younger children.

The limited attention spans of young children necessitated the development of a more elaborate training and testing procedure than is needed with adults. Extensive pre-testing was required to design a story-based category learning task and engaging tasks for the testing process. Pilot studies revealed that the procedures are too demanding for children younger than five years of age, and even for older children must be spread across sessions on two consecutive days. Rather than rely on an implicit comparison to the adult literature, we included an adult sample that followed the same procedures used with the children.

Method

Participants

Participants were 27 kindergarten children between the ages of five and six, and 23 Vassar College students participating through an introductory psychology research requirement. Participants in each age group were randomly assigned to the learning or control conditions.

Stimuli

The stimuli were designed to resemble friendly-looking alien creatures and varied on the dimensions of torso width and arm length. Figure 1 shows stimuli with extremes on these dimensions; intermediate values were defined at equal intervals between extremes. All stimuli had yellow bodies, green feet, blue hands, and a pink nose.

For the learning condition, two categories were created and identified by the nonsense labels *Fip* and *Zug*. The Fips had longer arms and narrower torsos, while the Zugs had shorter arms and wider torsos. For each category there were three possible values on each dimension, for a total of nine possible members of each category. Of the eighteen different possible stimuli, fourteen (seven in each category) were used in the experiment. Stimuli were printed out on yellow paper, laminated, and glued onto felt with a black oval-shaped background. A 155-cm X 74-cm board covered in black felt served as the background for the story. To enhance the interaction of the children with the materials and make the story more interesting, felt props were also used. These props represented various objects and devices described in the story. For instance, when it was explained that the Zugs trained by lifting moon rocks and eating a diet of fuzzy pickles and purple pretzels, participants would be asked to place moon rocks, fuzzy pickles, and purple pretzels alongside the Zugs.

Figure 1. Examples of the stimuli.

Procedure

The learning condition. Those who learned to distinguish Fips and Zugs did so over the course of two, one-on-one sessions with an experimenter. Learning occurred in the context of a story, told using the large felt board and felt props, about two teams of four aliens, the Fips and the Zugs, who compete in an alien Olympics competition. The story is designed to hold a

young child's attention so as to allow the experimenter to highlight the differences between the two categories in the context of an interactive dialogue rather than by direct instruction. For example, the long-armed Fips more easily get tangled in a cargo net while climbing, but their narrow torsos make them less likely to get stuck in an obstacle course. Interactivity is introduced by inviting the participant to help construct each scene. At several points in the script the participant is also asked to sort the aliens into categories, to allow provision of feedback as learning progressed.

On the second day of the learning condition, the story was continued. It concludes with a final competition, which results in a tie. The participant is told that he or she will get to stage one last game to settle the tie, but that first there are some other games to be played. These other games are the three primary data gathering tasks.

The participant gave similarity judgments for all fifteen possible pairs of six aliens, which include four that the participant had learned to categorize during the story telling (two from each category) and two not seen before (one from each of the two categories). Pre-testing indicated that fifteen judgments is an upper limit on five-year-olds' attention. The novel stimuli provide a check on whether what has been learned is a generalizable category. In the similarity judgment procedure one picture is placed at the left end of a long felt strip marked off into distinct intervals that allowed scores from 0.5 to 8.5 in 0.5 intervals. The participant is asked to place the other item according to how similar it was to the first item, with more proximal placement indicating greater similarity. The participant is trained on the task using pictures of different breeds of dogs. Pre-training continued until the judgments were being made reliably and with confidence. Once the system was understood, we presented the fifteen pairs of aliens. The experimenter recorded the judgment by reading the position of the center of the stimulus in relation to the marks on the strip.

In the second task, participants viewed twenty-one pairs of stimuli, presented simultaneously on a Macintosh Powermac G3 or Powerbook G3 using SuperLab Pro 1.75 software. The same six stimuli used in the similarity judgment task were used here as well. In addition to the fifteen pairs presented in that task, an additional six pairs were presented, comprised of each of the six stimuli presented with its identical twin. Careful training using pictures of flowers ensured that participants understood that a "same" response

required the stimuli to be identical. Participants answered by pressing clearly marked keys on a keyboard. A colorful feedback screen indicated whether the response was correct. These screens were designed during pre-testing so as to assure that the children wanted to produce the "correct" screen and did not like the "incorrect" screen.

For the third and final task each participant was asked to sort a slightly larger set of fourteen stimuli into two groups, the Fips and the Zugs. To the eight stimuli used in the story, and the two added during testing, we added four more, two from each category. Pilot studies suggested child sorting becomes unreliable when more than fourteen stimuli were included. This final task provides data concerning whether participants in the "learning" condition actually did learn the category distinction, and if so how well they extend the concept to new instances.

The control condition. Participants in the control condition performed the same three tasks as those in the learning condition but did not learn the story or receive any information about categories or types of aliens. Because they had not learned to categorize them, we could not refer to them by name. The only change in the tasks required by this difference was to the sorting task instructions, which simply asked that the aliens be put into two groups according to which ones seem to go together.

Results

Similarity judgments. A 2 (age: child vs. adult) by 2 (group: learning vs. control) by 3 (pair type: Fip-Fip, Fip-Zug, Zug-Zug) analysis of variance with repeated measures on the third variable yielded a highly significant main effect of pair type ($F(2, 90) = 81.140$, $MSE = 1.004$, $p < .0001$) and a highly significant interaction between condition and pair type ($F(2, 90) = 10.473$, $MSE = 1.004$, $p < .0001$). The between-category pairs were judged overall to be less similar than the within-category pairs, and the between-category pairs were also judged to be less similar by the learning groups than by the control groups, a clear case of expansion at the category boundary following learning. There is no interaction with age (see Figure 2.) No other effects were statistically significant.

Same-different judgments. This task yielded two dependent measures, proportion of errors and mean response time. Single-sample t tests demonstrate that all four groups performed the same-different task better than chance. A 2 (age:

Figure 2. Mean similarity judgments by both learning and control groups for each of three pair types (FF, FZ, ZZ). Higher numbers indicate greater dissimilarity

child vs. adult) by 2 (group: learning vs. control) by 3 (pair type: identical, same category non-identical, different category) analysis of variance with repeated measures on the third variable on the proportion of errors yielded a significant main effect of age ($F(1, 46) = 4.611$, $MSE = .045$, $p < .04$) and a highly significant main effect of pair type ($F(2, 92) = 23.095$, $MSE = .027$, $p < .0001$). Children made more errors than adults (.221 vs. .146) and different category pairs produced fewer errors (.057) than identical pairs (.218) or same category non-identical pairs (.275). No other effects were statistically significant.

A 2 (age: child vs. adult) by 2 (group: learning vs. control) by 3 (pair type: identical, same category non-identical, different category) analysis of variance with repeated measures on the third variable on the response times yielded significant main effects of age ($F(1, 45) = 8.823$, $MSE = 12859202$, $p < .005$) and pair type ($F(2, 90) = 5.399$, $MSE = 1932184$, $p < .007$), and a significant interaction of age and pair type ($F(2, 90) = 7.748$, $MSE = 1932184$, $p < .001$). Adults were significantly faster than children overall (2679 msec. vs. 4577 msec.), but this difference was due entirely to the non-identical pairs (both same and different category), which were also faster overall than the identical pairs. No other effects were statistically significant.

Sorting task. An item was considered correctly sorted if it was placed with the majority of the items of its category. This allows characterization of sorts by control participants as correct or incorrect. If one of the groups was

sufficiently larger than the other at the completion of the sorting, it might contain a majority of items from both categories. In that case, the larger majority was said to define the category and thus what counted as correct and incorrect in the two categories. A 2 (age: child vs. adult) by 2 (group: learning vs. control) analysis of variance on the number of items incorrectly sorted yielded significant main effects of age ($F(1, 45) = 9.032$, $MSE = 2.603$, $p < .005$) and condition ($F(1, 45) = 13.683$, $MSE = 2.603$, $p < .001$). The interaction approached significance ($F(1, 45) = 3.846$, $MSE = 2.603$, $p < .06$). Children made more errors than adults and control groups made more errors than learning groups, with control children making by far the most errors. Single-sample t tests demonstrate that only the children in the control condition performed this sorting task no better than chance.

Discussion

The finding, based on similarity judgments, that both adults and children in the learning condition show the same pattern of expansion at the category boundary when compared with participants in the control condition is consistent with the idea that changes to the metric of similarity space may mediate concept formation in an age-independent fashion. The results thus provide encouragement to seek similar evidence from work with still younger children, and to pursue that idea that adjustments to the metric properties of similarity space constitute a general phenomenon in category learning. Unfortunately, the failure to find evidence for expansion using the same-different task suggests that this procedure is not a good candidate for extension to younger ages. We had hoped that there would be differential changes in speed of responding between experimental and control groups, even in the absence of differences in errors, but found none of the necessary interaction effects for that measure either. Clearly, other task candidates, like the match-to-sample technique (e.g., Smiley and Brown, 1979), will have to be explored. At least one finding from the same-different task bears noting, however. The fact that identical pairs and different pairs from within the same category produced the same high level of errors for both adults and children (over 20%) suggests just how difficult the discriminations were between items, and is at least consistent with the hypothesis that expansion effects at the boundary reflect perceptual discrimination learning rather than

solely higher-order cognitive changes (Livingston, et al., 1998).

One of the more interesting theoretical -- and empirical, for that matter -- questions going forward will be how the operation of a similarity metric modification process like the one described here maps onto other patterns observed in the development of the child's system of concepts. We earlier highlighted the similarities between the concept learning of adults and children, but interesting differences have been noted and discussed in the developmental literature. For example, how does one square a compression-expansion mechanism with variations in criteria for classification, which have been said to shift from thematic to taxonomic (Smiley and Brown, 1979), or perhaps from basic-level taxonomic to thematic and then to superordinate-taxonomic (Gelman, Coley, Rosengren, Hartman, and Pappas, 1998). To address this issue more fully would require a more detailed analysis than is possible here, but two possibilities are immediately apparent. The first is that there is an important difference between perceptual categorization and conceptual categorization (Mandler, 2000), and that the processes we are describing apply only to the former. This is a highly controversial distinction (see the numerous commentaries that follow Mandler's paper), but if correct it would make it all the more important to find ways to pursue evidence for compression-expansion effects in toddlers and infants, for whom high-level conceptual processes are still poorly developed. The other possibility is that there is but a single process, mediated by changes in similarity metrics, and that variations in organizational structure, whether identified as thematic, taxonomic, holistic, analytic, or what-have-you, reflect shifts in the pattern of attention given to objects and events in the world, shifts that establish the basic dimensionality of the similarity space into which objects are sorted on a given occasion.

Conclusion

The successful demonstration of learned expansion in children shows that the modification of psychological similarity space that occurs in adult category learning operates very early in life and may indeed constitute a fundamental mechanism in concept acquisition. We suggest that further work is needed to extend these results to still younger children, and to resolve important theoretical issues about how

the compression-expansion process is related to known developmental changes in concept learning during the childhood years.

Abstract

A largely accepted view in the categorization literature is that similarity-based reasoning is faster than theory-based reasoning. In the current study, we explored whether theory-based categorization behavior would continue to be observed when people are forced to make category decisions under time pressure. As a specific test of the theory-based view to category representation we examined the causal status hypothesis, which states that properties acting as causes are more important than properties acting as effects when categorizing an item. Subjects learned four categories of items composed of three features and learned causal relations between those features. In two experiments we found that participants gave more weight to cause features than to effect features even under rapid response conditions. We discuss implications of these findings for categorization.

Introduction

When posed with categorization tasks in everyday life people recruit information from a variety of sources. In general, previous work on categorization has focused on two sources of information: similarity and theories. One family of categorization theories has centered on the notion of similarity (e.g., Kruschke, 1992; Nosofsky, 1986; Smith & Medin, 1981; Rosch & Mervis, 1975). On this view concept learning and use is based on computing the similarity between an object to be categorized and a stored representation of a category (e.g., exemplars, Nosofsky, 1986; or prototypes, Hampton, 1995).

An alternative view assumes that people have theories that embody relations between properties and influence categorization behavior (Carey, 1985; Keil, 1989; Murphy & Medin, 1985; Rips, 1989). An illustrative example comes from Keil's (1989) discovery experiment. When presented with an animal that had the appearance and behavior of a horse but the insides and lineage of a cow, adults would categorize the animal as a cow. This behavior suggests that

lineage has a special status above and beyond perceptual features, presumably reflecting the importance of lineage in our lay theory of biology. Similarly, Medin and Shoben (1988) showed that people would rather accept a square cantaloupe than a square basketball, presumably because "being round" is more central in naïve theories of physics (i.e., the domain in which basketballs are grounded) than in naïve theories of biology (i.e., the domain in which cantaloupes are grounded).

The similarity-based and theory-based views are not necessarily incompatible (e.g., Sloman & Rips, 1998). In fact, many proponents of either view allow for, or even advocate, the operation of both kinds of processes (e.g. Sloman, 1996; Smith & Sloman, 1994). However, these proposals typically put the two views on unequal footing. A persistent bias present in these 'hybrid' models is that similarity-based categorization is primary. For instance, in the developmental literature, it has been argued that theory-based mechanisms cannot precede similarity-based mechanisms in development because theories must be acquired through similarity-based mechanisms (Quine, 1977; Vygotsky, 1962; but see Keil, Smith, Simons, & Levin, 1998). Thus, only after sufficient experience has been obtained may theories be developed and used, amending (or supplanting) similarity-based information.

In addition to the idea that similarity-based categorization is developmentally primary, there is a notion that similarity-based information is accessed more rapidly, and perhaps more automatically, than theory-based information. This assumption may be motivated by the observation that novices (e.g., children) use similarity-based reasoning and thus it is a somehow simpler mode of reasoning (cf. Keil et al, 1998). Smith and Sloman (1994) make this argument explicit by assuming that theory-based reasoning is a type of rule-based reasoning, arguing that rule-based reasoning is, "more analytic and reflective than similarity-based categorization" (pp. 377-378).

To test this assumption Smith and Sloman designed a study to examine the effect of time constraints on theory-based (or rule-based) categorization. Smith and Sloman's subjects performed a forced-choice task in which each item consisted of a description of an object paired with two possible categories (task and stimuli adapted from Rips, 1989). Each item had one response that corresponded to a rule-based (i.e. theory-based) decision and one that corresponded to a similarity-based decision. For example, "Circular object with a 4 inch diameter" could be categorized as a pizza or a quarter. Calling this object a pizza would signify theory-based understanding of the minting process whereas calling this object a quarter would signify a similarity computation because a circular 4-inch object is more similar to quarters than to most pizzas (but see Nosofsky & Johansen, 2000). Rips (1989) found that people tended to choose the theory-based response. However, when asked to respond as quickly as possible, subjects in Smith and Sloman's study failed to reproduce this result. Only when instructed to talk aloud while categorizing did subjects tend to answer in accordance with the theory-derived rules. Thus, Smith and Sloman concluded that a "...possible constraint...is that the situation encourage people to articulate and explain their reasons for categorization, rather than encourage rapid judgments" (p. 383).

One problem with this interpretation is that the use of either similarity or theories resulted in subjects accepting bizarre objects as category members. For instance, participants had to decide whether a circular object with a 4-inch diameter that is silver colored is a pizza or a quarter. This is a rather strict test of theory-use and may not represent a naturalistic situation in which to test the influence of speed.

More recent studies have suggested that theory-based categorization may be at least as fast as (and perhaps as automatic as) similarity-based categorization. For example, Lin and Murphy (1997) pitted perceptual similarity against knowledge of an object's function during speeded categorization. For instance, an object with a loop was either described as a tool used to hunt animals where the loop is placed around the animal's neck, or a pesticide sprayer where the loop was used to hang it when not in use. Thus, the loop should have been viewed as central to the category in the former condition and more peripheral in the latter condition. Even when category responses had to be made within a one-second deadline, or when the picture of the object to be categorized was presented for only 50ms and then masked, subjects continued to be influenced by domain knowledge (e.g., the object's described function).

Palmeri and Blalock (2000) reported a similar pattern of results. Extending the findings of Wisniewski and Medin (1994), they had subjects categorize drawings supposedly drawn by children described as either "creative" or "non-creative." Subjects were able to categorize using this background knowledge (e.g., by the amount of emotional

expression) even when the pictures were shown for only 200ms. Their study demonstrated that theory-use did not require lengthy periods of reflection.

The main goal of the current study was to build upon these recent findings and to examine speeded theory-based categorization at a finer level. As a specific test of the theory-based view we have chosen to examine the causal status hypothesis (CSH; Ahn, Kim, Lassaline, & Dennis, 2000; Ahn, 1998). This hypothesis was developed in response to the valid criticisms that specific mechanisms underlying theory-based categorization had not been explicated. CSH states that features of an object that act as causes in one's domain theory are more important than features that act as effects, *ceteris paribus*. This measure, referred to as *causal depth*, makes explicit why some features are more central to one's theory than others.

As a test of the CSH, Ahn et al. (2000) provided subjects with novel categories that possessed features at different causal depths. When asked to classify possible category members, each of which was missing a single characteristic feature, subjects rated those missing an effect feature as a better category member than those missing a cause feature. In the current study we employed a similar methodology to test the effects of time pressure on the causal status effect.

Experiment 1

Method

Adapting the paradigm from Ahn et al. (2000), our stimuli consisted of four fictional animals (see Fig. 1). Each animal was described as possessing three features. The features were described as having a causal chain structure such that feature A causes feature B, and feature B causes feature C.

It is crucial to ensure that, in the absence of causal information, the three features did not vary in salience. Otherwise, any obtained causal status effect could not be solely attributed to the causal background knowledge but could instead be attributed to some other factor (e.g., physiological feature versus behavioral feature). To eliminate this possibility we pre-tested the stimuli on a separate set of subjects, using the animal descriptions without the explicit causal information. Subjects were then asked to rate the likelihood of category membership of items missing a single feature (see Fig. 2). The results of this pre-test showed no significant differences between the ratings of items missing the first feature, items missing the second feature, and items missing the third feature (all p 's > .4). Thus, we concluded that the features were equated for a priori strength.

In the categorization tasks used by Ahn et al. (2000), subjects were allowed to view the animal descriptions (along with the causal structure information) while they were making their category judgments. To allow for

speeded responses, subjects in our study were instead required to learn and memorize the four animals, their features, and the causal relations between the features. First, subjects were given the opportunity to study the description of each animal at the beginning of the experiment. While studying each description subjects were instructed to "write about how you think each feature causes the next," in an attempt to force subjects to think causally about the features (instead of as a simple ordered list). To help subjects further learn the items, they were then presented with 6 blocks of trials, during which they were prompted with the name of one of the animals and were required to select (using a mouse-click) the features of that animal from an array containing the features of all 4 animals. They were required to select those features in the appropriate causal order. Successfully responding to the entire set of animals twice allowed subjects to move on to the next block. In the first two blocks responses were unspeeded, while in the last four blocks responses had 5-second deadlines (any response not meeting the deadline was counted as incorrect). This speeded-learning procedure was added so that the novel causal background knowledge would be sufficiently internalized, thereby approximating real-life lay theories. In addition, on half of the blocks, subjects were asked for the causal relations in the forward order (e.g. A, B, C) and on the other half in the backward order (e.g. C, B, A). The order manipulation alternated across blocks and subjects, always beginning with a forward block.

Figure 1: A sample animal with causal links

Once subjects completed these six blocks they proceeded to the experimental transfer task. Subjects were presented with items missing a single feature and were asked to rate the likelihood that the item belonged to its target category on an 8-point scale (with 1 being "Definitely Unlikely" to 8 being "Definitely Likely"). Features of each transfer item were presented in a triad as shown in Figure 2, with the position of the features randomized.

There were 4 blocks of trials in the transfer task. In two of the blocks, subjects were instructed to answer as quickly as possible. In the other two blocks, they were told to take as much time as needed. The speed condition alternated across blocks and was counterbalanced across subjects.

For the unspeeded trials we expected to find results similar to those of Ahn et al. (2000). That is, items missing the terminal effect feature should be rated as more likely category members than those missing the initial cause feature. The critical question was whether this causal status effect would disappear during the speeded trials, as suggested by Smith and Sloman (1994).

Figure 2: A sample transfer item from Experiment 1

Results and Discussion

Before analyzing the subjects' category ratings, we verified the instructional speed manipulation. The RTs in the speeded blocks ($M = 1560\text{ms}$) were indeed significantly faster than the RTs in the unspeeded blocks ($M = 3202\text{ms}$), $p < .05$, Tukey's HSD.

Figure 3: Results from Experiment 1

The results for subjects' categorization responses are summarized in Figure 3. A 2 (speed condition: speeded vs. unspeeded) X 3 (item type: missing first feature vs. missing second feature vs. missing third feature) repeated measures ANOVA was performed on the data. We observed a significant main effect of item type, $F(2, 56) = 22.69$, $p < .0001$, demonstrating that subjects categorized in accordance with the causal status hypothesis. In addition, we observed no main effect of speed, $F(1, 28) = 2.89$, $p > .05$, and the speed X item type interaction was also not significant, $F(2, 56) = 1.03$, $p > .05$.

Planned comparisons were carried out to examine differences between item types. In both the speeded and unspeeded conditions items missing the third feature were rated significantly higher than those missing the first or second features ($p's < .05$, Tukey's HSD). The difference between items missing the first feature and those missing the second feature was not significant ($p's > .05$, Tukey's HSD), possibly because the second feature also served as a cause of another feature, making the difference between the first and the second feature less pronounced (see also Kim and Ahn, 2002).

Overall, these results demonstrate that it is possible to categorize using causal knowledge even when time for lengthy reflection is not allowed. It is tempting to contrast our findings with those of Smith and Sloman (1994). In their experiment, subjects needed unspeeded conditions and to talk aloud while making the judgment in order to demonstrate theory-based behavior. It is possible that the paradigm used by Rips (1989) and Smith and Sloman (1994) created a situation in which theory-use was more difficult to apply than our situation (see above). Nevertheless, our findings clearly question the assertion that theory-use is relegated to situations in which reflection and analytic thought is permitted.

Experiment 2

In Experiment 1, subjects were simply asked to respond as quickly as possible to the "speeded" items. Given this freedom, some subjects responded very quickly but others responded significantly more slowly. Although the speed manipulation we used in Experiment 1 is naturalistic, in that participants carried out what they thought to be a rapid decision making process, forcing participants to respond within a specific deadline would ensure uniform time pressure across all subjects. Therefore, in Experiment 2, we imposed stricter control over subjects' response times by enforcing deadlines on their category decisions.

One methodological complication with establishing appropriate response deadlines is that it is difficult to determine beforehand whether a particular deadline is short enough to challenge the categorization system but not so short as to make accurate responses impossible. That is, if the speeded condition does not show the causal status effect, it can be because theory-based reasoning does not take place during rapid categorization or because the deadline is too short to produce any reasonable responses.

For this reason, we also tested whether similarity information could be used under similar deadlines. By testing both kinds of knowledge, the causal status effects can be compared to similarity-based categorization at each deadline. In this way it can be inferred whether any breakdown of the causal status effect is due to the inability to complete the processes necessary for theory-based

categorization or if reasonable responses at that deadline are impossible for both kinds of categorization.

Similarity is frequently calculated based on how many attributes an item has in common with other members of the category (e.g., Tversky, 1977). Therefore, as a similarity-based determinant for feature weighting, we manipulated the relative base rates of each feature within a category (i.e., what percentage of category members possess a feature), a measure also known as *category validity*. In fact, category validity has been shown to be positively correlated with typicality ratings (Rosch & Mervis, 1975).

Experiment 2 contains a similarity condition that provides category validity information in much the same way causal information was provided in Experiment 1. Using this condition as a point of comparison, and with the addition of strict response deadlines, we hope to provide a more rigorous test of the causal status effect under speeded conditions.

Methods

Subjects in the Causal condition were given the same stimuli and accompanying causal information as used in Experiment 1. Subjects in the Base-Rate condition were given the same stimuli but were instead given information about the relative base rates of each feature. Thus, each category was described as having three features (e.g. A, B, and C) such that 100% of category members possessed feature A, 80% of possessed feature B, and 60% possessed feature C. In our parlance, the Causal condition represents a theory-based situation whereas the Base-Rate condition represents a similarity-based situation. Paralleling the results of Experiment 1, items in the Base-Rate condition missing the third (60%) feature should be rated as better category members than those missing the first (100%) feature. This is because those missing the third feature share more features with more category members than those missing the first feature.

The learning phase for the Causal condition was identical to that used in Experiment 1. Subjects in the Base-Rate condition did not have to generate explanations but instead categorized exemplars into one of the four animal categories. For this task, each exemplar always possessed the first feature of its category, possessed the second feature on 80% of the trials, and the third feature 60% of the time (thus mirroring the stated base rates). When a given feature did not appear in an exemplar, a feature from one of the other animals was substituted. Feedback was given after each trial.

Blocks of 30 such trials alternated with blocks of the "selection task" used in the Causal condition. The only difference was that features were selected in an order (forward or backwards) dictated by their base rate rather than their position in the causal chain.

The transfer phase for both conditions was nearly identical to that used in Experiment 1 except for a modified speed manipulation. Instead of an instruction to respond quickly, Experiment 2 employed a signal-to-respond technique (Lamberts, 1998). Thus, each trial presented the feature triad (Fig. 2) for a specified duration (see below). When the triad was removed from the screen subjects made their response. If a response was made more than 300ms after the disappearance of the triad, subjects were told to respond more rapidly.

There were four blocks of trials. Each block used one of four presentation durations (1500ms, 750ms, 500ms, and 300ms). These blocks were ordered randomly for each subject.

Figure 4: Results from Causal Condition

Results and Discussion

The results from the categorization task can be seen in Figures 4 and 5. A 2 (knowledge condition: Causal vs. Base-Rate) X 4 (speed condition: 1500ms vs. 750ms vs. 500ms vs. 300ms) X 2 (item type: missing first feature vs. missing third) ANOVA was performed with repeated measures on the latter two factors. We observed a significant main effect of item type, $F(1, 58)=15.14$, $p<.0005$, that did not interact with knowledge condition, $F<1$, demonstrating that both background conditions had the predicted effect on categorization behaviors. No significant main effect of speed was observed, $F(3, 174)=1.88$, $p>.05$, but this main effect must be interpreted in light of a significant interaction between speed and item type, $F(3, 174)=6.26$, $p<.001$, which will be further examined below. No significant main effect of background condition was observed, $F(1, 58)=3.43$, $p>.05$, and this factor did not interact with either of the other two factors. The three-way interaction between background condition, speed, and item type also failed to reach significance, $F(3, 174)=1.93$, $p>.05$.

Planned comparisons were carried out to determine at what response deadlines the background information had a

significant effect on categorization. For simplicity, we only report comparisons between items missing the first feature and those missing the third, the differences that CSH predicts to be the largest. For the Base-Rate condition, items missing the first (100%) feature significantly differed from items missing the third (60%) feature in the 1500ms condition, $t(29)=3.43$, $p<.005$, and the 750ms condition, $t(29)=2.41$, $p<.05$, but not in the 500ms, $t(29)=.3$, $p>.05$, or 300ms, $t(29)=1.59$, $p>.05$, conditions. In the Causal condition, items missing the first (initial cause) feature differed from those missing the third (terminal effect) feature in the 1500ms, $t(29)=2.22$, $p<.05$, the 750ms, $t(29)=2.86$, $p<.01$, and the 500ms conditions, $t(29)=2.06$, $p<.05$, but not the 300ms condition, $t(29)=.81$, $p>.05$.

Figure 5: Results from Base-Rate condition

In light of these results, it is clear that theory-driven causal knowledge can be utilized to categorize stimuli under even faster conditions than those created in Experiment 1. Subjects in this experiment were able to categorize according to their theory even when allowed only 800ms to view the exemplar and make a response. This is impressive considering that this condition was 200ms condition faster than the speeded condition used by Lin and Murphy (1997; Experiment 4) – their stimuli were pictures whereas ours were verbal descriptions. Furthermore, our results indicate that the base rate information, which has been considered a key determinant of similarity (Rosch & Mervis, 1975), did not result in differential responses under this deadline. The results taken together provide strong evidence that theory-based categorization cannot be slower than similarity-based categorization.

Conclusion

The current experiments demonstrated two important findings: First, theory-based categorization, as measured by the causal status effect, did not necessarily require excessive periods of deliberation in order to exert an influence on

behavior. Second, the latencies at which theory-use is possible are comparable to those of similarity-use. These findings bolster the idea that use of similarity is not necessarily more primary than theory-use. Instead, it appears that people's use of theories and similarity may be inexorably intertwined, not just during development (Keil, et al., 1998) but during the course of a single category decision as well.

One open question concerns the type of reasoning that takes place when subjects actually categorize transfer items. Was any causal reasoning taking place during the transfer tasks, or were subjects simply retrieving pre-compiled notions about feature importance derived during learning? Future studies on this issue will help us develop more detailed processing accounts of theory-based categorization. The current results, at the very least, clearly demonstrate that previously acquired causal knowledge influences later categorization judgments even when rapidly categorizing objects.

Case, Word Order, and Language Learnability: Insights from Connectionist Modeling

Abstract

How does the existence of case systems, and strict word order patterns affect the learnability of a given language? We present a series of connectionist simulations, suggesting that both case and strict word order may facilitate syntactic acquisition by a sequential learning device. Our results are consistent with typological data concerning the frequencies with which different type of word order patterns occur across the languages of the world. Our model also accommodates patterns of syntactic development across several different languages. We conclude that non-linguistic constraints on general sequential-learning devices may help explain the relationship between case, word order, and learnability of individual languages.

Introduction

In language acquisition, children are faced with many formidable tasks, yet they normally acquire most of their native language within the first five years of life. One of the most difficult of these tasks involves mapping a sequence of words onto some sort of interpretation of what that sequence is supposed to mean. That is, in order for the child to understand a sentence, she needs to determine the grammatical roles of the individual words so that she can work out who did what to whom. Although the children appear to bring powerful statistical learning mechanisms to bear on the acquisition tasks (e.g., Saffran, Aslin, & Newport 1996), the existence of linguistic universals common across radically different languages (Greenberg 1963) points to the presence of innate constraints on such learning. Without such constraints, it becomes difficult to explain why there are few, if any, Object-Subject-Verb (OSV) languages (van Everbroeck, 1999) even though in principle such a language appears to be as good as any other. In this paper, we propose that these constraints may arise from non-linguistic limitations on the sequential learning of statistical structure, and examine how this perspective may shed light on how children learn to map the words in sentences onto their appropriate grammatical roles. There are two major ways in which languages signal syntactic relationships and grammatical roles—word order (WO),

and case markings. In a strict WO language like English, declarative sentences follow a Subject-Verb-Object (SVO) pattern. It is the occurrence of the subject in the first position, and the object in the second, that allows the hearer to comprehend who did what to whom. In contrast, languages such as Russian or Japanese allow multiple word orders and rely on case markings to disambiguate subjects from objects. For instance, *Masha lubit Petyoo* (SVO), *Petyoo lubit Masha* (OVS), and *Lubit Petyoo Masha* (VOS) are all grammatical in Russian and all mean *Mary loves Peter* (albeit with different emphases on the constituents), due to the nominative *-a*, and accusative *-u* case markers.

While long-standing theories describe acquisition of language through an innate language acquisition device (e.g., Pinker, 1995), an alternative approach that is gaining ground is the adaptation of linguistic structures to the human brain rather than vice versa (e.g., Christiansen, 1994; Kirby, 1998). On this account, language universals may reflect non-linguistic cognitive constraints on learning and processing of sequential structure, rather than constraints prescribed by an innate universal grammar. Previous work has shown that sequential-learning devices with no language-specific biases are better able to learn more universal aspects of language as compared to aspects encountered in rare languages (e.g., Ellefson & Christiansen, 2000; Christiansen & Devlin, 1997; Van Everbroeck, 1999, 2001).

Here, we examine the ways in which case markings and word order may function as cues for a sequential learning device acquiring syntactic structure. In simulation 1, we model different word orders, and hypothesize that typologically common languages should be easier to learn by a sequential-learning device than the more rare ones. We expand on this idea in simulation 2 by studying the performance of networks trained on languages of varying degrees of case markings and flexibility. Finally, in simulation 3, we establish that our trained networks are able to mimic syntactic performance of children learning English, Italian, Turkish, and Serbo-Croatian (Slobin and Bever, 1982).

Acquisition of Word Order

Generative linguists have long relied on parameter setting to explain how children acquire the distinct patterns of their native language. For instance, it has been assumed that the way a child knows to generate SVO and not SOV English sentences is through the setting of a VO/OV parameter (Neeleman, 1994). This account has been unsatisfactory because it does not account for many observed correlations; for instance, OV languages typically have flexible word orders (Koster, 1999). More generally, parameter theory has been largely unable to account for the asymmetries and patterns in the distribution of world languages. Why, for instance, are the most common word orders SOV, SVO, and VSO (Greenberg 1963: Universal 1)? Why do verb-final languages almost always have a case system (Greenberg 1963: Universal 41)? And even more fundamentally, why do case languages have flexible word orders to begin with? It is our position that these observations can be at least partially accounted for by examining the learnability of languages from the viewpoint of sequential learning.

Generative linguistics also leaves largely unexplained the process children use to actually set the parameters. With regard to word orders, an explanation espoused by Pinker (e.g., 1995) involves the so-called Subset Principle. According to the Subset Principle, children take the most conservative strategy and so, by default, assume a fixed order. Alternative word orders are only accepted if a child is exposed to these orders, at which time a free word order parameter gets switched on. Under this assumption, FWO languages are predicted to be more difficult to learn. Although the idea that all languages are initially approached as having strict word-order (SWO) was popular in the sixties and seventies (Slobin, 1966), Slobin and Bever (1982) conclude that the primacy assigned to word order was unduly influenced by languages such as English.

There is ample evidence that children learning a strict word-order language such as English never leap to the conclusion that it is a free-word order language (Pinker 1995). While Pinker has used this evidence for reinforcing parameter-setting—the reason children never leap to such conclusions is because a word-order parameter has been set—we suggest an alternative explanation. Simply, children learning English generally do not produce non-SVO sentences because non-SVO sentences are incomprehensible in English. In the absence of case markings, *Kicked John Bill* is ambiguous as to who did the kicking. Children learning English, use the statistical properties of the language to learn that word order is a reliable cue to syntactic relationships. Children learning a case-based language such as Russian, make a similar observation about case markings. This view obviates the need for a default strategy. What is important is that there exist some set of cues to in-

dicade syntactic relationships—there is nothing inherently special about word order or case markings. In short, we posit that a major reason for the observable asymmetries among the world's languages is that certain patterns make a language more easily learnable by a general sequential-learning device, ensuring the proliferation of such a language in the human population.

Simulation 1: Exploring the Learnability of Case and Word Order

In the view that the frequency of certain WOs is correlated with their learnability, we hypothesized that typologically rare languages will be more difficult to learn by a sequential-learning device than the more common languages. To test this prediction, we trained simple recurrent networks (SRNs: Elman, 1990) on a total of 14 artificial grammars, reflecting the 6 possible strict word orders (SWO) and a flexible word order (FWO), with or without the presence of case markings.

Method

Networks Ten SRNs were used in each condition. The networks were initialized with random weights in the interval $[-0.1, 0]$.¹ Each input to the networks consisted of a distributed representation of a word, spliced with a case marker. Words were represented by 20-unit randomly generated bit-vectors. Although some vectors were bound to be close in the representation space, random assignment to words assured that any such interaction would not bias the results. Having words represented by random vectors may seem odd considering the complex phonology that underlies human languages. However, for present purposes such a representation seems to work just as well as phonological (e.g., van Everbroeck 2001), while dramatically decreasing training time. Case markings (nominative, accusative, dative, and genitive) were represented by a four-bit vector appended to the word vector. This made for a total of 24 input units. There were seven output units, corresponding to the grammatical roles the network was supposed to predict: subject, direct object, indirect object, genitive noun, verb, or end-of-sentence. In all simulations, the learning rate was set to 0.1, and momentum to 0.01. Each SRN had 30 hidden units and 30 context units.

Materials The lexicon contained 300 nouns and 100 verbs. This noun-to-verb ratio is generally consistent with human languages (e.g., British National Corpus). The verbs were evenly divided into intransitive, transitive, and ditransitive categories. As illustrated in Table 1, each grammar included three

¹It was found that the slightly inhibitory starting weights provided for better performance across the board. A similar conclusion was reached by van Everbroeck (2001).

Table 1: A Sample SOV Grammar Used to Generate Training Corpora

S → Intransitive [.35] Transitive [.35] Ditransitive [.3]
Intransitive → NP-nom V-intrans
Transitive → NP-nom NP-acc V-trans
Ditransitive → NP-nom NP-acc NP-dat V-ditrans
NP → N N N-gen [.25]

types of sentences: intransitive, transitive, and ditransitive. A sentence consisted of noun phrases (NP) and one of three verb classes. Twenty-five percent of noun phrases contained a noun in the genitive form (e.g., *John's brother*). The simplest sentence generated by such a grammar was a simple intransitive: e.g., *John walks*. The most complex sentence contained 7 words: *Mary's friend gave Peter's key [to] John's brother*. A fully flexible grammar was identical to the strict WOs except the order within each element was randomly varied from sentence to sentence. In an effort to model the languages as naturalistically as possible, we modeled genitives based on Greenberg's (1963) universal 2: in typically prepositional languages (SVO and VSO) genitives generally follow the governing noun, while in postpositional languages (SOV), the reverse is true. We modeled the remaining three word orders with genitives following the noun. We also added a genitive case-marking to SWO-no case languages. Without this, it was impossible for the networks to discern governing nouns from genitives. This addition is motivated by the observation that even normally case-less languages have some form of genitive case markings (e.g., in English: *Mary's house*) (van Everbroeck, 2001).

Procedure We used a crossover design of 7 word orders (6 strict, and one flexible), by two case conditions (with or without case) resulting in 14 training corpora. For each condition, we generated 3,000 random sentences of the appropriate order. Such a corpus occupies a very small part of the possible sentences that can be generated by the corpus. For instance, 9 million different sentences are possible for a transitive SOV configuration (300 x 300 x 100).

The networks were trained for 100,000 sweeps (input/output pairs), corresponding to about 7 passes through the corpus. During each training sweep, the network was presented with a word, and depending on the condition, a case marking. A corpus of 200 novel sentences was created for testing. In the testing corpus, 50% of words were completely new—ones to which the network has never been exposed. Performance was measured by assessing the network's ability to map a given word to its correct grammatical role. During testing, the network's highest-activated output unit was compared to the expected output. If the units matched, the word was marked

Table 2: Network performance and Language Distributions

Word Order	Words Correct – No Case Condition (%)	Attested Frequency (%)
SOV	90	51 (most w/cases)
VOS	85	8
OVS	80	0.75
OSV	74	0.25
Flexible	65	0 (all w/cases)

Note. Attested language frequencies taken from Van Everbroeck (1999).

as being correctly mapped.

It may seem that providing the networks with direct mapping from word to grammatical category is not ecologically valid. After all, it has long been recognized that kids are not given sufficient ostensive cues to syntactic relationships and word meanings. No one explains to the child after each encountered sentence that word *A* referred to the “do-er” and word *B* to the “do-ee”. However, Tomasello and colleagues have shown that children are able to use pragmatic cues such as eye gaze to help figure out which object is being referred to (Tomasello & Akhtar, 1995). Twenty-four month olds show understanding of adult intentions in inferring meanings of novel verbs (Tomasello & Barton, 1994), and 18-month old children are able to learn new words in non-ostensive contexts (Tomasello, Strosberg, & Akhtar, 1996). Such use of pragmatic cues enables children to map words onto meanings and correctly infer who did what to whom. Considering that our networks live in a purely linguistic world, the method of direct mapping seems reasonable.

Results

All networks trained in the case condition were able to map 100% of the words to the correct categories. When case was not available, the network performance roughly corresponded to attested language frequencies (Table 2). Only two caseless WOs obtained nearly perfect performance: SVO and VSO (99%). There, however, appears to be a discrepancy. While SOV is the most common WO, it is outperformed by both SVO and VSO. According to Greenberg's Universal 41, however, the great majority of SOV languages have case, and most caseless languages turn out to be either SVO or VSO (e.g., English, Welsh). This finding supports our learnability hypothesis: verb-final languages presumably have a case system because reliance on WO results in suboptimal learnability.

The likely reason SOV-no case grammars did not achieve perfect accuracy is because they contained two unmarked nouns prior to the verb. Since the networks learn to map different types of verbs to different argument constructions, verb-final grammars are at a disadvantage—in these grammars the

grammatical role that provides the most information about what is to come, is received last (van Everbroeck, 2001). The poor performance of VOS is due to the intervening indirect subject in ditransitive sentences. We should also note that even though FWO-no case languages perform poorly, their performance is consistently above chance. This can be explained by the networks' learning to map familiar verbs to intransitive, transitive or ditransitive word schemas.

These simulation results confirm the idea that FWO-case languages are no more difficult to learn than common SWO-no case languages such as SVO and VSO, counter to predictions of the subset principle. The difficulty associated with learning a FWO language without case markings is underscored by typological evidence, suggesting that such languages use case markings to signal grammatical relationships (Payne 1992).

Simulation 2: The Impact of Case on Word Order Flexibility

In natural languages, case markings are not wholly deterministic. For instance, Slavic languages such as Russian and Serbo-Croatian, contain a number of nouns which, perhaps for historical reasons, do not take case markings. Additionally, because these markings often take the form of suffixes, they change the phonology of words. This results in potential phonological ambiguity. For instance, in Russian *stali* is either the genitive form of *steel* or a conjugated verb meaning *we stopped*. By examining the effects of varying cases on different word orders, we hoped to show that (1) even probabilistic case markings improve performance for FWO languages, and (2) case markings do not improve performance for languages that already rely on WO.

Method

Networks Ten SRNs were used for each condition. The initial conditions and training details were the same as in Simulation 1.

Materials We generated five artificial grammars varying on the salience of case markings—from only genitive markings, to full case markings. A grammar with case marked 50% of the time corresponded to a language in which 50% of case markings are possibly phonologically ambiguous, or a language in which certain of nouns do not take on case markings. Five more grammars varying on strictness of word order—from a completely flexible order, to a completely strict one (SVO). The word orders approximated distributions found in natural languages (Italian, and Turkish: Slobin & Bever 1982); Polish: Jacennik & Dryer 1992). The two conditions were crossed, for a 5x5 matrix. As in simulation 1, 3000 sentences were generated for each condition.

Figure 1: Network performance in simulation 2 for increasing degrees of case markings as a function of word order.

Procedure Each group of networks had case cues added to the sentences based on case condition. The testing proceeded as in Simulation 1.

Results

As expected, SWO languages such as English and Italian were little-benefited by case (Figure 1). In contrast, the probabilistic addition of case markings to FWO languages consistently improved performance. The slightly lower performance of Italian is due to it having a more flexible word order than English (see Table 3). To compensate for possible ambiguities, Italian relies heavily on prosodic and contextual information (Slobin & Bever, 1982) which was not available to our networks. In summary, the precise nature of the cue: case, or WO, does not seem to matter. Neither needs to be primary.

Simulation 3: Interactions between Case and Word Order Flexibility in Development

In this simulation, we demonstrate that networks trained on corpora similar to those used in simulation 2 are able to mimic syntactic performance of children learning English, Italian, Turkish, and Serbo-Croatian. Slobin and Bever (1982) tested 48 children divided into 8 age groups (24-52 months). Each child was tested on their ability to demonstrate familiar actions (e.g., *scratch*, *bump*, *pick up*) using familiar toy animals after hearing a transitive language in their native language. The authors hypothesized that Turkish, English, and Italian-speaking children would have the easiest time due to the consistent, unambiguous case markings available in the case of Turkish, and the consistent word-order information available in English and Italian. Children

Table 3: Word Order Distributions for Simulation 3

Language	Words Order	Cases
English	100% SVO	Genitive only
Italian	82% SVO, 2% SOV, 11% VSO, 5% OVS	Genitive only
Serbo-Croatian	55% SVO, 16% SOV, 16% VSO, 3% VOS, 2% OVS, 8% OSV	Full for non-SVO For SVO: 55% nom, 55% acc, 100% dat, 70% gen
Turkish	48% SOV, 25% SVO, 13% OVS, 8% OSV, 6% VSO	Full

acquiring Serbo-Croatian would have a more difficult time due to its more ambiguous case markings, requiring them to pay attention to word-order as well as cases.

Method

Networks The networks and training details were identical to simulation 2. We used 12 SRNs in each condition, mirroring the number of subjects used by Slobin and Bever (1982).

Materials We created 4 types of grammars motivated by the four languages used in the study. English was modeled as being 100% SVO, and having only genitive case markings. The word orders for the remaining languages were modeled based on the data provided by Slobin and Bever's (1982) corpus of adult speech, reflecting the linguistic input available the children.

Although Turkish does not have an explicit nominative case, it was found that such a marker was necessary in this simulation. In the absence of semantic information and case markings, the networks must rely on the syntactic position of a word to correctly identify its category. However, in a relatively FWO language such as Turkish, this information is ambiguous. Without a nominative case, both verbs and subjects are unmarked, and the network naturally has trouble telling them apart. In contrast to these networks, children rely on semantic information, in addition to syntax, to tell apart verbs and nouns. In other words, a Turkish child knowing the meanings of "dog" and "sniff", will not confuse the two even when "dog" is an unmarked agent in the sentence.

Serbo-Croatian has all four of the cases we were modeling, however, only masculine and feminine nouns take on accusative and nominative markings. Sentences containing one or more neuter nouns are typically ordered as SVO. We did not have data on the proportion of neuter nouns in Serbo-Croatian or the percentage of SVO sentences containing such nouns. It was estimated that about 55% of SVO sentences would contain one such noun, therefore case

Figure 2: The pattern of performance across training for Turkish, English, Italian, and Serbo-Croatian in simulation 3

Table 4: Percentage correct performance for grammatical sentences in a given language in the Slobin and Bever (1982) study.

Age	Language			
	English	Italian	Serbo-Croatian	Turkish
24-28	58	66	61	79
32-36	75	78	58	80
40-44	88	85	69	82
48-52	92	90	79	87

markings were deleted from 55% of nouns in SVO sentences. Serbo-Croatian neuter nouns do have dative case-markings, hence the datives are marked 100% of the time. However, plural neuter nouns are not declined in genitive constructions. If plural genitive nouns are used an estimated 30% of the time, then 70% of SVO sentences will have genitive case markers.

Procedure Training proceeded as in simulation 1. The extent of training was varied for networks corresponding to different age groups. Testing was done following the procedure employed by Slobin and Bever (1982). We used transitive sentences using only words which the networks have seen during training. Performance was quantified by measuring the percentage of subjects and objects the network identified correctly, and averaging the data with the overall percentage of words correctly identified.

Results

The networks' performance (Figure 2) closely matched Slobin and Bever's (1982) data (Table 4). As predicted, networks trained and tested on Turkish had the easiest time mapping words onto grammatical roles. Networks trained on Serbo-Croatian,

had the most difficult time, highlighting the higher processing-cost associated with having to pay attention to WO and case markings. This pattern of results runs counter to the subset principle since the latter predicts case-languages to be more difficult to acquire. Performance on Italian was slightly worse than on English, reflecting the more flexible WO of Italian. It is predicted that with the addition of prosodic and semantic cues, the performance of Italian would more closely parallel that of a fully SWO language such as English.

Conclusion

Our findings confirm that learnability of languages may be a major factor in the frequency of certain language types. In the view of language as an organism (Christiansen, 1994), languages which are easily learnable by the human sequential-learning device proliferate, while languages not easily learnable die out or never come into existence. Our simulations suggest that all that is needed to learn syntactic relations is a reliable cue: case, or word order—neither needs to be primary. As such, no parameter-setting or subset principle is needed to account for the data. These results also provide added support for a connectionist approach to studying acquisition and evolution of language.

The simulations described here have several notable limitations. The sentences used for training were admittedly simple. Although simple intransitive, transitive, and ditransitive sentences are very frequent in speech, natural languages are rife with more complex structures such as relative clauses and embedding. Offsetting the simple grammars, however, were the limited cues available to the networks, which relied solely on distributional information of grammatical categories. In contrast, children routinely use semantics and prosodic cues, and even more subtle cues such as differential word length of nouns and verbs (Cassidy & Kelly, 1991—see Christiansen & Dale, 2001, for a review). It is therefore quite remarkable that relying only on word order or case, the performance of the networks was near-perfect for common language types.

Abstract

We report on an experiment that investigated how people naturally communicate with computational devices using speech and gaze. Our approach follows from the idea that human-human conversation involves the establishment of common ground, the use of gaze direction to indicate attention and turn-taking, and awareness of other's knowledge and abilities. Our goal is to determine whether it is easier to communicate with several devices, each with its own specialized functions and abilities, or with a single system that can control several devices. If conversations with devices resemble conversations with people, we would expect interaction with several devices to require extra effort—both in building common ground and in specifying turn-taking. To test this, we observed participants in an office mock-up where information was accessed on displays through speech input only. Between groups, we manipulated what participants were told: in one case, that they were speaking to a single controlling system, and in the other, that they were speaking to a set of individually controlled devices. Based on language use and gaze patterns, our results suggest that the office environment was more efficient and easier to use when participants believed they were talking to a single system than when they believed they were talking to a several devices.

Introduction

One approach to human computer interaction is to improve the usability, user experience, and intuitiveness of technology by creating natural user interfaces. Here, *natural* refers to interactions that are like those people have with one another. Such is the goal of multimodal or attentive systems (Maglio, Matlock, Campbell, Zhai & Smith, 2000; Oviatt & Cohen, 2000), and speech and conversational interfaces (Maybury, 1997). Understanding cues in conversation, language use, perceptual abilities, and expectations is vital to building systems that can be used with little training.

Advances in technology are resulting in smaller, cheaper, and more pervasive computational systems than ever before. But are we ready for this surge of electronics and information? No longer confined to desktop or laptop machines, computational systems will soon extend across numerous "information appliances"

that are specialized for individual jobs and embedded in the everyday environment (Norman, 1998). If point-and-click graphical user interfaces (GUI) have enabled wide use of PCs, what will be the paradigm for interaction with pervasive computing systems? As natural human-computer interfaces and pervasive systems converge, what form will technology take?

To address these questions, we explored the design of a pervasive system with speech input in an office setting. We were concerned specifically with conversational cues that people rely on when interacting with the system. Some evidence suggests that people can attribute human-like or social qualities to computers with which they interact; for instance, networked computers described as physically close to the user are judged as more helpful than those described as physically distant (Reeves & Nass, 1996). Although people do not treat computers as true conversational partners (Yankelovich, Levow & Marx, 1995), these sorts of results suggest that people apply natural ways of interacting to situations in which the conversational partner is a computer or other computational device.

Our main concern is whether it is easier for people to talk to a single system or to a collection of devices. In a previous study of a speech-controlled office, we found behaviors and attitudes depended on whether users received simple command recognition feedback (a blinking light) from the various devices that performed tasks or from a single, central location (Maglio, Matlock, Campbell, Zhai & Smith, 2000; Matlock, Campbell, Maglio, Zhai & Smith, 2001). In that study, users were faced with simple office tasks (such as looking up information, dictating a letter, and printing a letter) to be completed using speech input only. To do this, users were given a set of physical displays dedicated to various functions (such as address book, calendar, and so on). Between groups of participants, we manipulated whether feedback was associated with individual displays or with the room as whole. This feedback manipulation was meant to suggest either central control or distributed control. Behaviorally, we found that regardless of condition, participants rarely addressed individual devices verbally, but they looked at the devices that they expected to display the results

before they spoke (Maglio et al., 2000). In a questionnaire aimed at uncovering attitudes toward the office, we found that participants in the central condition were more likely to rate their interactions with the office as being similar to interactions with people than were those in the distributed condition (Matlock et al., 2001). The results show that although people judge the central controller to be more like a person, they interact with devices individually in both cases, looking at devices when they speak. One design implication is that the feedback provided by blinking lights enables natural user-computer interactions. But the question of whether it is easier to speak to a single system or to multiple devices remains.

Let us first consider how people use language to communicate. There are many theories. A popular view is that discourse is a shared activity whereby two or more individuals cooperate to build and achieve understanding (Clark, 1996). This joint activity view implies that the meaning of an utterance is determined not only by what the speaker wishes to say to the listener, but also by context. This includes speaker's beliefs about the situation, (e.g., what speaker assumes the listener knows about the context), common ground (e.g., shared history), and listener's ability to accurately interpret the speaker's message (e.g., listener is paying attention). For example, imagine that it's early afternoon and you have just come back from a favorite lunch spot. A friend looks at you and asks, "Was it crowded?", where *it* refers to the restaurant. It is no problem to use the indexical *it* because the friend can assume that you know which restaurant is being asked about. The question can even be reduced further by simply asking, "Crowded?", and you are still likely to understand what is meant. This type of coordinated interaction is so common and natural that people do not think twice about it.

Given context's role in understanding, the joint activity view implies that the process of conversation also involves verbal (e.g., prosodic) and non-verbal (e.g., gaze) cues to convey meaning. Feedback is critical for supporting user interactions with computational systems (Perez-Quinones & Sibert, 1996); for instance, appropriate acknowledgments (e.g., "uh-huh") based on prosodic cues in users' speech can improve user evaluation of the system (Tsukahara & Ward, 2001). Likewise, gaze provides important cues to attention and turn-taking in group interactions (Kendon, 1967; Argyle & Cook, 1976).

Hypotheses

Following the joint activity view of conversation, our main hypothesis is that given complex tasks and their dependencies on one another, participants who interact with a single system will be more likely to establish context and then assume the system shares it than will

those who interact with several devices. In human-human communication, the number of words used by participants in a conversation decreases over time, suggesting that the more common ground, the easier the communication (Clark & Wilkes-Gibbs, 1986). Thus, if people treat the system in the central condition in some ways like a single other person and they treat each of the devices in the distributed condition in some ways like several other people, participants may feel that they need to establish common ground with the single system only once but that they need to establish common ground with each of the devices individually, and we can measure this by counting words used—specifically, words that refer to things mentioned previously. Moreover, if establishing common ground is easier in the central condition than it is in the distributed condition, many predictions follow; for instance, participants should make fewer mistakes in the central, and participants should be more engaged with the central system, as shown by gaze.

An alternative to the joint activity view is that discourse is simply a process of transferring information without reference to context or to those involved. On this view, meaning is derived from what is spoken without concern for who the speaker is or what the situation is. If this is the case, maintaining separate functions in separate devices might make it easier for users to keep the various functions straight, as each device naturally conveys its own range of available options (e.g., email device for email). Thus, on this view, common ground is not constructed over time but is established once by what the device can do. If this is the case, talking to a single system ought to be more difficult than talking to multiple devices, as the single system does not make the options apparent.

Experiment

The goal of the experiment was to investigate whether and how language use and gaze would differ between participants interacting with a central system and those interacting with a distributed system. Our study was done in a mock office in which participants completed office tasks under the illusion that they were controlling what was displayed on four specialized screens. This sort of mock-up or *Wizard-of-Oz* method is often used to investigate user expectations and performance with speech-based systems (Dahlback, Jönsson & Ahrenberg, 1993; Gould, Conti & Hovanyecz, 1983). The *Wizard-of-Oz* method relies on human controllers behind the scenes to create the appearance of an intelligent system, mocking up displays and interaction results to collect performance data.

In one condition, the experimenter instructed participants to speak to a system that controlled all the devices, and in the other, to speak to the individual devices. Unknown to participants, two other

experimenters in a separate room watched and listened, controlling what was displayed from a palette of many possible screens. The rules of the game were for the experimenters to simply behave intelligently: if what the participant was trying to do was clear from speech and other context, the system was to respond appropriately. The experimenters controlling the system were blind to which participants were given which instructions.

Method

Between two groups of participants, we manipulated *only* the instructions. In the central condition, participants were repeatedly told that they were to talk to a single computer system that displayed information on four displays. In the distributed condition, participants were repeatedly told that they were to talk to four separate information devices. Tasks were identical in both cases: sending and receiving email, updating address information, scheduling appointments, arranging a flight, and registering for a conference. Information was displayed the same way in both cases.

Participants Eighteen participants (13 females and 5 males) were recruited from summer student interns and office staff at our research lab, and paid for their time.

Materials and Apparatus Our office mock-up contained four 15-inch liquid crystal displays (LCDs) arranged on an L-shaped desk. Embedded in the bezel of two of the LCDs were pinhole video cameras, which enabled eye gaze and body position to be easily recorded. A third camera mounted on the wall above the room recorded an overview of the scene. Each display was dedicated to a different function or task: email, calendar, travel planning, and address book.

There were two sets of instructions, one for each condition. Instructions for the central condition told participants to talk to the "BlueSpeak system", a single computer system that controlled four displays. Instructions for the distributed condition told participants to talk to a set of "BlueSpeak devices", four separate devices that ran autonomously. In both cases, the script was written as a memo from a fictitious manager named Bob Wilson. The memo told the participant that he or she was to be his temporary assistant (or temp) for the day. It asked the temp to register Bob for a conference, add a new address to his address book, get a flight from San Jose to New York, reschedule a meeting, and request a vegetarian meal on the flight. The script purposely did not specify how to issue commands. It included statements such as "You will need to arrange my travel to New York and from San Jose", "I need to register for the XYZ Conference," and "Make sure my calendar is updated". Such language made for many possible ways of making

Table 1. Tasks completed by participants.

Update Address Book
open new address form
dictate name, address, city, state, zip, phone, email
Register for XYZ Conference
find XYZ information screen
obtain Bob's personal information
compose new email to XYZ
dictate name, email, phone, credit card
add XYZ to calendar
Find and Reserve Flights
find airline reservation screen
interact with reservation "system"
dictate cities, dates, non-stop, under \$400
reserve/book itinerary
obtain Bob's personal information
dictate name, email, credit card
add flights to calendar
Reschedule Meetings
obtain Kathy's personal information
compose new email message to Kathy
read Kathy's response
modify Kathy's meeting
Notify Bob of Status
compose new email to Bob
read Bob's response
adjust calendar, cancel meeting
modify airline reservation
find reservation for Bob
specify vegetarian meal

requests. In addition, a few tasks were given in email messages sent to the temp during the course of the session. Table 1 shows the set of tasks and subtasks each participant was expected to carry out.

Procedure Participants read the instruction sheet and were told their input was valuable because it would help ensure that the "BlueSpeak system" or the "BlueSpeak devices" would be tested on a wide range of voices. Participants were then taken into the "Office of the Future", and asked to test out their voices by reading a short passage to the system in the central condition or to the devices in the distributed condition. Participants were then told to carefully read the memo left by Bob Wilson. In all cases, participants were instructed to speak naturally and to do the best they could. They were told that there was no right or wrong way to speak to the system or the devices, and that if they were not understood, to try speaking differently. After issuing a command, the system did not give any feedback other than displaying the result of the request.

Results

All participants successfully completed the session. Few problems arose and on average it took participants 13 min 43 sec to complete all tasks. Data analysis targeted language-use and eye-gaze during the session. Only reliable differences are reported, except as noted.

Language Qualitatively, participants spoke to the system in a variety of ways. For instance, requests to send email included, "Let's send an email to Kathy Webster," "I need to send an email now – I would like to send it to k webster at ibm dot com," "Email k webster at ibm dot com," and "Write an email to Kathy Webster". Requests to get Bob a vegetarian meal on included, "Request vegetarian meal," "Vegetarian meal," "Let's make this a vegetarian meal", and "Special request, vegetarian meal for this flight".

More precisely, transcribed utterances in both conditions were examined for certain characteristics of language use. First, requests were placed into four categories: imperative, elliptical, first person, and question (cf. Maglio et al., 2000). Imperative requests are commands, such as, "update the address book", "view addresses", "register for conference". Elliptical requests contain no a verb, such as, "XYZ conference", "new entry", and "Kathy Webster". First person requests include either a singular or plural first person subject, such as "let's read this email", and "I want a vegetarian meal". Question requests include queries such as, "can I check my email?" and "are there any other flights available?". Figure 1 shows the breakdown of requests for both conditions. There were more imperatives (central, 70.4%; distributed, 80.3%; $\chi^2 = 9.75, p < 0.01$) and more ellipticals (central: 11.8%; distributed: 16.9%; $\chi^2 = 4.16, p < 0.05$) in the distributed condition, and there were more first persons (central, 13.3%; distributed, 2.8%; $\chi^2 = 26.9, p < 0.01$) and questions (central, 4.5%; distributed, 0.0%; $\chi^2 = 16.4, p < 0.01$) in the central condition.

Second, we examined how participants verbally addressed individual devices. Specifically, we counted the number of times a device was specifically addressed by name, such as, "Address book, what is Kathy Webster's address?". The proportion of requests containing an addressee was greater in the distributed condition than in the central condition (central, 1.7%; distributed, 14%; $\chi^2 = 40.87, p < 0.01$).

Third, we examined the way participants recovered from errors. We were interested in how requests were reformulated after an initial attempt had failed. To take one example, the most problematic part of the script was ordering a vegetarian meal for the flight (last task in Table 1). Overall, in the central condition, the meal request was restated 9 times. In the distributed condition, it was restated 13 times. Three participants in the distributed condition were unable to complete this task at all and eventually gave up.

Fourth, we looked at the way participants relied on previously established context. For example, when interacting with the system, a participant might say "register Bob Wilson for XYZ conference" and then a short time later say, "add event to calendar", referring implicitly to the conference. In this case, the

Figure 1. Percentage of the time participants used different types of requests.

participant assumes the system is following the discourse, and that once established, the context (the conference event) need not be repeated. We calculated the proportion of statements that assumed context available in a previous statement across all participants in each condition (see Figure 2). Overall, participants in the central condition assumed that the system would understand the context more often than participants in the distributed condition (central, 7.0%; distributed, 1.4%; $\chi^2 = 14.50, p < 0.01$).

Finally, we charted how language use changed during the course of a session. Each participant's discourse was cut in half, based on the task breakdown in Table 1. The number of times each participant relied on established context (as defined previously) was tallied separately for the first half and for the second half (see Figure 2). No difference between central and distributed conditions was found for the first half (central, 5.5%; distributed, 2.2%; $\chi^2 = 2.45, NS$), but a reliable difference was found for the second half (central, 8.5%; distributed, 0.6%; $\chi^2 = 13.59, p < 0.01$).

Behavior and Gaze Behaviors—including actions participants took and where they looked—were analyzed in terms of the task breakdown in Table 1. Specifically, all overt physical actions taken by participants were transcribed from the videotapes and time-stamped. From these data, we extracted number of tasks, time taken per task, number of gazes or looks to task-relevant and to task-irrelevant locations, and number and kind of the errors made. For all results, scores falling outside two standard deviations from the mean were removed and replaced by mean scores; these outliers constituted 8% of the scores.

Mean completion time was 13 min 17 sec for the central condition and 14 min 10 sec for the distributed condition. To calculate the time taken for each individual action for each participant, the time taken for each task (e.g., "Update Address Book," "Register for Conference," etc.) was divided by the number of actions (e.g., "open address book", "find Bob's personal information", etc.) actually taken to complete

Figure 2. Percentage of time participants relied on established context.

the task. A difference was found between central and distributed conditions on the mean time to take an action in the address book task (central, 21.1; distributed, 27.1; $t(16) = 3.18, p < 0.01$), and a marginal difference was found between the mean times to take an action in the flight reservation task (central, 54.0; distributed, 73.4; $t(16) = 1.71, p < 0.11$).

Unnecessary actions and omitted actions constituted errors. Number of errors was calculated for each participant. Percentage of errors was determined by dividing the total number of errors by the total number of actions taken for each participant. Overall, there were 20% errors in the central condition and 16% in the distributed condition. This difference was not reliable.

Finally, we examined where people looked and when they altered their gaze. In particular, we counted the total number of times a participant looked at a specific display when making a request for which that display would be expected to show a result (see also Maglio et al., 2000). For instance, we counted times when a participant looked at the address book and then said "Michael Smith's address," but not times when the participant would say "Michael Smith's address" before looking at the address book. The percentage of the time each participant looked at the appropriate display when taking action was calculated by dividing the number of appropriate looks by the number of actions. As shown in Figure 3a, a difference was found between the two conditions (central, 80%; distributed, 96%; $t(16) = 2.79, p < 0.05$). In addition, we counted the number of times a participant looked away from a display they were using to complete an action (again, normalizing with respect to total number of actions). As shown in Figure 3b, a difference was found between the two conditions (central, 53%; distributed 10%; $t(16) = 2.39, p < 0.05$).

Discussion

In summary, participants interacting with the single system had an easier time than those interacting with multiple devices. Specifically, the data show

Figure 3. Percentage of time participants (a) shifted gaze to display before speaking, and (b) away from display while speaking.

1. dominant use of the imperative in both cases, and more use of first-person and question forms in the central case
2. less verbal addressing in the central case
3. less reformulation—and more successful reformulation—of requests in the central case
4. more reliance on context in the central case, which increased over time
5. slightly faster overall completion time for the central case, and significantly faster for certain tasks (updating address book, reserving a flight)
6. less of the time, gaze shifted to the appropriate display before speaking in the central case
7. more of the time gaze shifted away from the appropriate display in the central case

Returning to our hypotheses, we can conclude that participants in the central condition relied more heavily on context they had established previously, shown by the number of times they implicitly referred to objects and information. This is what we expected given the joint activity view of discourse (Clark, 1996). It follows that participants in the central condition behaved more like they were speaking to a single entity than those in the distributed condition. The way participants addressed displays and shifted gaze also supports this conclusion. Participants in the central condition addressed individual devices less frequently, suggesting that they were less likely to be speaking directly to devices. Moreover, participants in the central condition shifted gaze to individual devices when starting a task less frequently, also suggesting that they were less likely to be speaking directly to individual devices. Finally, participants in the central condition more frequently shifted gaze from device to device while engaged in a task, suggesting that they were unconcerned with keeping eye contact with a specific device. Taken together, these results suggest that participants in the central condition behaved more like they were engaged with a single entity than those in the distributed condition.

Conclusion

The present study was intended to investigate how people speak to computational systems. Controlling whether users believed they were speaking to a single centralized system or to several separate devices, we found a centralized system was more efficient and easier to use than separate devices in several ways. Not surprisingly, the main difference was that users of the central system treated the system as a single entity whereas users of the separate devices treated the devices as independent entities. By relying on a single controller, users in the centralized condition were more likely to reuse conversational context than users in the distributed condition. Moreover, because they interacted with a single entity, users did not need to divide attention across several conversational partners.

What are some implications for Clark's joint activity view of conversation? It may initially seem misguided to apply this theory to human-computer interaction, for it was intended to deal with human-human interaction only. And after all, computers and other devices are not *true* conversational partners because they are controlled by their users and cannot really engage in conversation. Nonetheless, Clark's theory was in fact predictive of behavior in this study, demonstrating that in this human-computer interaction context, many of the same assumptions about human-human interaction apply.

What are some implications for the design of future computing environments? First, for the sorts of tasks considered here, it is clear that a single controller is to be preferred over multiple devices. Thus, when designing a system that requires a user to coordinate information and activities among a set of distinct displays or information sources, it would be appropriate to provide the user a single point of contact with the overall system, as this would allow the user to establish an ongoing relationship with a single entity. Second, because maintaining context seems critical for efficiency (and possibly for ease of use as well), providing users with appropriate state information would likely encourage them to rely on established context. Third, because users tended to fix their gaze on individual devices in the multiple device condition, gaze cues (in addition to language cues) might be useful in helping the system determine level of engagement and to disambiguate referential statements, but cannot be relied on completely in the single controller case. Fourth, if assumptions about common ground can be manipulated by instructions, then the physical design of a system should be carefully considered. For example, putting several screens in the environment with the same physical size and characteristics might suggest multiple devices, whereas one large display and a few smaller displays might appear to be a single system with one point of contact and several output monitors.

Fifth, giving devices obvious ways of collecting information from the room, such as a visible camera, allows users to understand what kind of common ground the system is likely to have. For instance, the camera may make users more likely to use gestures (e.g. pointing) to reference information. Finally, providing users with a single point of control need not have consequences for implementation; it might simply be enough to *tell users* to speak with a single device.

On the Potential of Epistemic Actions for Self-Cueing: Multiple Orientations Can Prime 2D Shape Recognition and Use

Paul P. Maglio (pmaglio@almaden.ibm.com)

IBM Almaden Research Center

University of Notre Dame

Abstract

Epistemic actions are physical actions people take more to simplify their internal problem-solving processes than to bring themselves closer to an external goal. Consider how when playing the video game Tetris, experts routinely rotate falling two-dimensional shapes more than is necessary to place the shapes. One reason for such apparently unnecessary actions is that they actually help the player make placement decisions. Such actions might facilitate placement decisions if additional previews of the shape afforded by rotating it provide information about the board, particularly when there is no direct perceptual match between the shape and the board at the time of decision. The study presented here tests the hypothesis that several distinct previews of a two-dimensional shape can improve a person's ability to recognize and use that shape when it is not correctly oriented at the time of decision. Results show that indeed task performance and recognition are faster with *two different* orientations than with only one. Thus, it is possible that Tetris players rotate two-dimensional Tetris shapes manually to see them in more than one orientation, as this can lead to faster decisions.

Introduction

People playing the video game Tetris often take actions that are not strictly necessary but that serve to simplify or speed up internal cognitive or perceptual operations (Kirsh & Maglio, 1994; Maglio & Kirsh, 1996). Playing Tetris involves maneuvering falling two-dimensional shapes into specific arrangements on the computer screen (see Figure 1). Even as players become faster with practice, they tend to over-rotate falling shapes, leading to backtracking as these over-rotations are corrected. To make sense of such backtracking, Kirsh and Maglio (1994) argued that sometimes physical rotation can serve the same purpose as mental rotation, effectively offloading mental computation onto the physical world (see also Clark, 1997; Kirsh, 1995; Maglio, Matlock, Raphaely, Chernicky & Kirsh, 1999). Such physical actions—taken to simplify internal cognitive computation rather than to move closer to the external goal state—are called *epistemic actions*.

Because shape identification can be facilitated when primed with orientations different from the target orientation (Cooper, Schacter, Ballesteros & Moore, 1992; Srinivas, 1995), and because numerosity judgments can be facilitated even when test stimuli are not presented at the same orientation as the originally learned patterns (Lassaline & Logan, 1993), memory for a target pattern might not require the retrieval cue be specifically oriented. Thus, the epistemic function of physical rotation in Tetris might be far more complex than is suggested by the simple idea that physical rotation can substitute for mental rotation, for instance, serving the function of cueing retrieval (Kirsh & Maglio, 1994). Because physically rotating a Tetris shape (which we call a *zoid*) provides the player two views of it (i.e., in each of two orientations), it is possible that seeing two different views makes retrieval of relevant information easier than does seeing just one. In fact, we found previously that when participants in a Tetris-like task are presented with two views of a zoid, the time taken to decide whether it fits a particular board is faster than when participants are presented with only a single view, but this does not depend on the orientation of the previews relative to one another (Maglio & Wenger, 2000).

There are at least three potential functions of rotation for self-cueing in Tetris. First, seeing the falling zoid in several different orientations may provide helpful information about the board, particularly when there is no direct perceptual match between zoid and board at decision time. That is, if the orientation of the zoid floating above the board does not match the orientation in which the zoid actually fits the board when the player must decide to place it, then having previously seen the zoid in the matching orientation might help the process of mentally matching zoid and board. Such an effect might be the result of having recently seen the zoid in its fitting orientation, basing the decision as to whether the zoid matches the board on memory rather than on mental rotation. Let us call this potential epis-

Figure 1: In Tetris, two-dimensional shapes fall one at a time from the top of the screen, landing on the bottom or on top of shapes that have already landed. There are seven shapes, or *zoids*—, , , , , , . As a zoid falls, it can be rotated, and moved right or left. The object of the game is to fill rows of squares all the way across. Filled rows dissolve and all unfilled rows above move down.

temic function of rotation, the *board-match* function.

A second potential function of rotation for self-cueing might be to provide advance information about the zoid itself, particularly when the several previews coincide with the orientation of the zoid at the time of decision. That is, if the orientation of the zoid floating above the board matches the orientation in which the zoid fits the board when the player must decide to place it, then having seen it previously in that orientation might make recognition easier. In this case, such an effect might be the result of a complex memory retrieval process in which multiple views of a shape lead to faster or more reliable recognition of it (see Maglio & Wenger, 2000). Let us call this potential epistemic function of rotation, the *zoid-retrieval* function.

A third potential function of rotation in Tetris might relate to motor processes rather than to memory or perceptual processes. Because physically rotating objects can facilitate or inhibit mental rotation under certain conditions, it is possible that mental rotation and physical rotation share at least some internal processes (e.g., Wexler, Kosslyn & Berthoz, 1998). Thus, the specific motor act Tetris players take in rotating the falling zoid might serve the purpose of coordinating motor processes with other internal processes to facilitate zoid placement decisions. Let us call this potential epistemic function, the *motor-process* function.

These three epistemic functions of action—the

board-match function, the zoid-retrieval function, and the motor-process function—are not mutually exclusive. All are possible reasons for the over-rotations observed in normal Tetris play. In this paper, we explore only the board-match function. Specifically, we test the hypothesis that seeing several different orientations of a falling zoid is better than seeing just one when the final orientation of the zoid does not match the region the zoid fits on the contour of the board. As noted, any such facilitation might result from matching the board to the memory of the previewed zoid rather than mentally rotating the zoid seen at test. Thus, our board-match hypothesis is a kind of memory-retrieval hypothesis.

Retrieval demands while playing Tetris can be thought of as *indirect* tests of memory in that they allow for effects of prior experience to be expressed without requiring explicit memory for the original experience (e.g., Richardson-Klavehn & Bjork, 1988). Tasks requiring explicit memory for the original event—such as old/new recognition or recall—are referred to as *direct* tests of memory. Because direct and indirect tests are differentially sensitive to orientation, object symmetry, and other physical aspects of visual objects (Srinivas, 1995; Srinivas & Schwoebel, 1998), the experiment presented here used both direct and indirect assessments of memory to determine how effective previews are under different retrieval demands. Because the effectiveness of memory cues generally depends on the time that elapses between presentation of cue and presentation of the item to be retrieved, we also investigated the effect of various delays between final preview and onset of test.

Method

To test whether two orientations of a falling zoid leads to faster performance in Tetris than one orientation does, we created a controlled experimental situation that shared many attributes with the game of Tetris but that allowed fine-grained control over the parameters of interest. In our experimental set up, a Tetris configuration (a Tetris board and zoid floating above it) is preceded either by none, one, or two previews of the zoid in either the same or different orientations. The participant's job is to quickly and accurately determine at the time of test whether the zoid floating above the board fits snugly on the board. Thus, the task creates situations similar to those faced by Tetris players during an actual game, and also requires responses similar to those required of players during an actual game. In all cases, in the final Tetris configuration, the zoid and the region it fits on the board contour (if it fits) are oriented

Figure 2: Three trial types used, from left to right: one preview, two previews in the same orientation, and two previews in different orientations. An "X" indicates display of an irrelevant zoid for the trial.

Figure 3: The second preview zoid is oriented properly relative to the board in the trial on the left but not in the one on the right.

differently, meaning there was no perceptual match between zoid and board at test (see Figure 2). In some cases, the last preview was oriented so as to fit snugly on the board contour without rotation, in which case memory for the previewed zoid might facilitate the fit/no-fit decision (see Figure 3).

Participants spent about three hours playing our experimental version of Tetris. Separate groups of participants were required either (a) to make judgments about whether a target zoid fit in an accompanying board (indirect test), or (b) to make this judgment *and* indicate whether they remembered seeing the test zoid in the set of zoids that were presented prior to the target (direct test). Between 0 and 2 previews of the target zoid were presented in a sequence of zoids prior to the target, and the orientation of these previews (when present) varied relative to the target. By placing the previews in a sequence of events prior to the test, we were able to manipulate the interval over which the preview would have to be retained in memory.

Participants

Twenty-nine participants were recruited from psychology courses and participated voluntarily in exchange for course credit: 15 in the indirect condition, and 14 in the direct condition. All participants reported normal or corrected-to-normal vision.

Design

The experimental design was fairly complicated so as to control as many factors as possible. As described, our main interest was in whether multiple previews of the zoid primed recognition and use better than a single preview when there was no perceptual match between zoid and board at test. In addition, we controlled whether the test zoid fit the test board, whether the preview zoids were in the same or different orientations, the time between preview and test, and whether memory was tested directly (asking whether the test zoid had been previewed) or indirectly (asking only for a fit/no-fit judgment).

More precisely, the experiment was conducted as a 4 (preview type: no previews, one preview, 2 previews same orientation, 2 previews different orientation) \times 2 (orientation of the last preview relative to the board: same, different) \times 3 (retention interval between last preview and target zoid, in frames: 0, 1, 2) \times 2 (zoid type: , ) \times 2 (status of target zoid relative to the board: fit, not fit) \times 2 (type of memory judgment at test: direct, indirect) mixed factorial design. All factors except type of memory judgment were manipulated within participants.

Materials

All zoids and boards were constructed from 20×20 pixel squares. Squares were outlined by light gray lines, 1 pixel in width, and were filled in solid black. The background for all displays was also solid black. All zoid types were composed of four blocks. All boards were six blocks in height and width. Four "fit" boards were defined for each zoid type, corresponding to four ways in which the zoid could be snugly placed. Each such board was used with equal frequency. Materials were displayed on a 33 cm VGA monitor controlled by a PC-compatible computer. Onset and offset of each display was synchronized to the monitor's vertical scan. A standard keyboard was used to collect and time (to $\pm 1ms$) responses.

Procedure

Participants were tested on two consecutive days, at approximately the same time each day, with each session lasting approximately 90 min. All sessions were conducted in a darkened room, with participants seated an unconstrained distance from the

monitor, and began with a five min period for dark adaptation. Participants were told that, on each trial, they would see a sequence of zoids presented very rapidly. The zoids in the sequence would begin falling from a location near the top of the screen: each successive zoid would appear below the one before to create a sequence of falling zoids much as in the Tetris game. Each zoid was present for 250 ms, and each sequence consisted of between five and seven zoids, with the actual number determined randomly (and with equal likelihood) on each trial. At some random point in this sequence, participants would be presented with a combination of a test zoid and board, and would need to make one of two types of responses, depending on whether they were in the indirect or direct memory condition.

In the indirect condition, participants had to decide whether the zoid presented at test would fit snugly into the board. Participants responded in the affirmative using the index finger of the dominant hand, and in the negative using the index finger of the non-dominant hand, pressing either the "z" or "/" keys on the lower row of the keyboard. In the direct condition, participants had to indicate with a single key-press both judgment about whether the presented zoid fit snugly in the board and memory for any occurrence of the test piece (in any orientation) in the sequence that preceded the target. Participants responded with the index finger of the dominant hand if the target piece fit and they remembered seeing this piece in the preceding sequence, with the middle finger of the dominant hand if the target piece fit and they did not remember seeing it in the preceding sequence, and with the index finger of the non-dominant hand if the piece did not fit. Speed and accuracy were emphasized equally.

Results

Note that participants quickly became very good at this task; by the end of the first day, overall error rate was below 3%, indicating a high level of skill. Now, to determine whether primes had an effect, correct reaction times (RT) were analyzed using two 2 (zoid type: \boxplus , \boxminus) \times 2 (preview: present, absent) \times 2 (status of the test zoid: does fit, does not fit) repeated measures ANOVAs, one for each test condition (direct, indirect). In both test conditions, presence of a preview speeded responses (indirect, 556 ms vs. 691 ms, $F_{(1,14)} = 11995.0$, $MSE = 23.04$; direct, 867 ms vs. 1008 ms, $F_{(1,13)} = 1095.75$, $MSE = 254.10$). Both conditions also showed faster responses when the test zoid fit relative to when it did not (indirect, 594 ms vs. 653 ms, $F_{(1,14)} = 43.67$, $MSE = 1214.50$; direct, 890 ms vs. 985 ms, $F_{(1,13)} =$

Figure 4: Preview-present trials: interaction of lag and fit status. Fit + indicates trials where the test zoid fit, and Fit -, where the test zoid did not fit. Lag is expressed in terms of the number of frames intervening between last preview and test zoid.

120.27, $MSE = 1039.34$). Finally, the effect of the presence of a preview was dependent on the status of the test zoid, with the preview effect being larger when the test zoid fit relative to when it did not (indirect, 140 ms vs. 131 ms, $F_{(1,14)} = 10.87$, $MSE = 31.12$; direct, 148 ms vs. 133 ms, $F_{(1,13)} = 5.08$, $MSE = 181.28$).

Having established that a preview made a difference, we next look to see whether having more than one preview made a difference, and whether the preview(s) had any interacting effects with other aspects of the design. The preview-present data were analyzed using two 2 (zoid type: \boxplus , \boxminus) \times 3 (number of previews: 1, 2) \times 2 (orientation of the preview relative to the test piece: same, different) \times 3 (lag, in frames, between the last preview and the test zoid: 0, 1, 2) \times 2 (status of the test zoid: does fit, does not fit) repeated measures ANOVAs, one for each of the test conditions. A first result was an effect of number of previews: participants were faster with two previews than with one (indirect, 542 ms vs. 562 ms, $F_{(1,14)} = 101.02$, $MSE = 353.96$; direct, 857 ms vs. 872 ms, $F_{(1,13)} = 15.75$, $MSE = 1172.30$). The

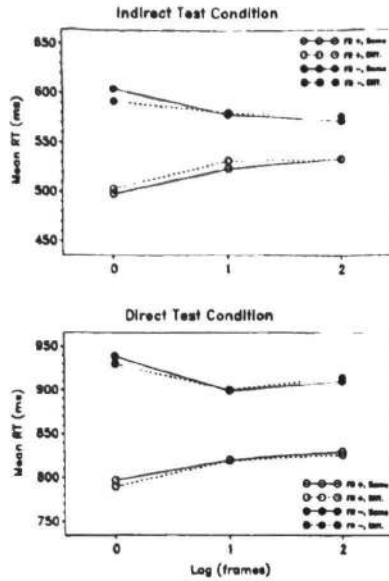

Figure 5: Preview-present trials: interaction of lag, fit status, and orientation of the test zoid.

lag between the last of the previews and the status of the test zoid interacted in both test conditions (see Figure 4): decreases in lag produced faster RTs when the test zoid fit (indirect, $F_{(2,28)} = 73.19$, $MSE = 379.39$; direct, $F_{(2,26)} = 21.72$, $MSE = 1488.90$) but produced longer RTs when the test zoid did not fit. Finally, there was an interaction among lag, status of the test zoid, and orientation of the preview relative to the test zoid (see Figure 5), though this interaction was reliable only for the indirect condition ($F_{(2,21)} = 4.21$, $MSE = 339.60$).

We next examined trials on which there were two previews. Half of these involved previews in one orientation and half involved previews in two orientations. Analysis revealed that seeing two orientations led to faster responses than seeing one orientation in both indirect (616 ms vs. 686 ms, $t_{(28)} = 4.23$) and direct (932 ms vs. 980 ms, $t_{(26)} = 4.18$) conditions.

If epistemic actions serve the mnemonic purposes we have suggested, then there might be a certain awareness on the part of the player as to mnemonic state while playing, which in turn suggests that the ability to monitor memory state may modulate the benefits of epistemic action. To assess this possibility, we examined the preview-present trials of the direct test condition, treating accuracy of memory

Figure 6: Preview-present trials, direct test condition: interaction of lag, number of previews, and accuracy of the memory judgment.

judgment as a random effect, using a 2 (memory accuracy: correct, incorrect) \times 2 (zoid type: \boxplus , \boxminus) \times 3 (lag between last preview and test zoid: 0, 1, 2) \times 2 (number of previews: 1, 2) repeated measures ANOVA. This analysis revealed the expected benefit of increasing the number of previews (899 ms for two vs. 946 ms for one, $F_{(1,24)} = 6.66$, $MSE = 1194.80$). It also revealed faster responses when participants accurately remembered the preview relative to when they did not consciously recall seeing a preview (855 ms vs. 997 ms, $F_{(1,24)} = 4.79$, $MSE = 96227.58$). Finally, there was an interaction among lag, number of previews, and the accuracy of the memory judgment (see Figure 6; $F_{(2,48)} = 4.02$, $MSE = 1851.61$).

Discussion

Our results show that when the test zoid and board are not oriented properly with respect to one another, one preview of the zoid in any orientation with respect to the board leads to faster responses than does no previews, and two previews lead to faster responses than does one preview. This was found for both indirect Tetris-like fit/no-fit judgment task as well as for direct memory recognition task. In addition, two previews with two different orientations produced faster responses than did two previews with the same orientation. Thus, under certain conditions, several orientations can prime two-dimensional shape recognition and use better than a single orientation can.

Note that response time was speeded up by a single preview in any of the three orientations relative to the test zoid and board. The benefit was not restricted to a preview that shared orientation with the test display. This finding is consistent with priming studies in which it was found that a prime need not be presented in the same orientation as the target to facilitate recognition or identification (e.g., Cooper, Schacter, Ballesteros & Moore, 1992; Srinivas, 1995). However, we have gone a step further than these by showing that *priming with several orientations is more effective than priming with a single orientation* under certain conditions.

The data also revealed that the benefit of previews, on trials in which the test zoid did fit, diminished as time elapsed between last preview and time of decision. This attenuation of the positive effects of previews suggests that the benefit of rotation for self-cueing may be restricted to a small window of time just prior to the final decision, which would be consistent with the reasonably rapid pace at which the game proceeds for skilled players. In contrast, on trials in which the test zoid did not fit, temporal proximity between last preview and judgment appeared to extract a cost, suggesting a strong specificity of the effect of previews to particular conditions of the game. Moreover, the data from the direct test condition revealed that accurate, conscious memory of a preview produced a benefit in responding, suggesting that players may have the ability to monitor their mnemonic state—as well as the state of the game—as play unfolds. One provocative idea is that epistemic actions may occur in response to players' assessment of a need for additional cueing.

Returning to the specific idea epistemic action in Tetris—the board-match function of rotation in particular—these results suggest that by rotating falling zoids, players may be able to effectively cue themselves, enabling quicker responses in a Tetris situation. Previous research has established various ways in which Tetris players take actions for their epistemic effects (Kirsh & Maglio, 1994; Maglio & Kirsh, 1996). The data reported here show that several previews of the falling zoid sometimes speeds up performance on a Tetris-like task, but the hypothesis that Tetris players over-rotate zoids in order to speed up performance is not directly tested. It remains to be seen whether actually taking the action of orienting the preview (i.e., physically rotating the falling shape) is a critical component of performance, independent of the presentation of the preview itself. It also remains to be seen whether the time-cost of making an extra move is more than compensated by the benefit in RT. We are exploring both questions.

Immediate Integration of Syntactic and Referential Constraints on Spoken Word Recognition

Abstract

We tested the hypothesis that syntactic constraints on spoken word recognition are integrated immediately when they are highly predictive. We used an artificial lexicon paradigm to create a lexicon of nouns (referring to shapes) and adjectives (referring to textures). Each word had phonological competitors in both form classes. We created strong form class expectations by using visual displays that either required adjective use or made adjectives infelicitous. We found evidence for immediate integration of form class expectations based on the pragmatic visual cues: similar-sounding words competed when they were from the same form class, but not when they were from different form classes.

Top-down constraints on word recognition

It is clear that we integrate top-down information when we interpret language. If someone tells us they put money in a bank, we understand that their money is in a vault and not buried next to a river. What is less clear is *when* and *how* we integrate top-down knowledge with bottom-up linguistic input.

One possibility is that language is processed in stages, with top-down information integrated after an encapsulated first-pass on the bottom-up input (e.g., Frazier & Clifton, 1996; Norris, McQueen & Cutler, 2000). The theory behind this genre of model is that optimal efficiency can be achieved by applying automatic processes that will almost always yield a correct result. In the rare event that the automatic result cannot be reconciled with top-down information, reanalysis would be required.

A second possibility is that top-down constraints are integrated immediately, with weights proportional to their predictive power (e.g., McClelland & Elman, 1986; MacDonald, Pearlmutter & Seidenberg, 1994; Tanenhaus & Trueswell, 1994). The theory behind constraint-based approaches is that a system can be made more efficient by allowing any sufficiently predictive information source to be integrated with processing as soon as it is relevant.

While a variety of results support constraint-based theories of sentence processing (see MacDonald et al., 1994), there is reason to believe that spoken word recognition is initially encapsulated from top-down constraints. Swinney (1979) and Tanenhaus, Leiman & Seidenberg (1979) provided the seminal results on this issue by examining whether all homophones are activated independent of context. Tanenhaus et al. presented participants with spoken sentences that ended with a syntactically ambiguous word (e.g., "they all rose" vs. "they bought a rose"). If participants were asked to name a visual target immediately at the offset of the ambiguous word, priming was found for associates both of the alternative suggested by the context (e.g., "stood" given "they all rose") and of homophones that would not fit the syntactic frame (e.g., "flower"). Given a 200-ms delay prior to the presentation of the visual stimulus, priming was found only for associates of the syntactically appropriate word. This suggests that lexical activation is initially based only on bottom-up information, and top-down information is a relatively late-acting constraint.

Tanenhaus & Lucas (1987) argued that this made sense given the predictive power of a form-class expectation. Knowing that the next word will be one of tens of thousands of nouns would afford virtually no advantage for most nouns (those without homophones in different form classes). Furthermore, expectations for classes like noun or verb might be very weak because modifiers can almost always be inserted before either class (e.g., "they just rose", "they bought a very pretty red rose"; cf. Shillcock & Bard, 1993).

Shillcock & Bard (1993) pointed out that there are form classes that should be more predictive than *noun* or *verb*, because they have few members: those made up of closed-class words. They examined whether /wud/ in a sentence context favoring the closed-class item, "would" (e.g., "John said that he didn't want to do the job, but his brother would, as we later found out"), would prime associates of its homophone, "wood", such as "timber" (compared with a context like "John said he didn't want to do the job with his brother's

wood, as we later found out"). They found priming for "timber" given the open-class context (favoring "wood") immediately after the offset of /wud/, but not given the closed-class context. The same result held when they probed half-way through the pronunciation of /wud/. This suggests the closed-class context was sufficiently constraining to bias the earliest moments of word recognition. A cloze test (in which participants were asked to supply the next word given the sentence contexts up to the word just prior to "would" or "wood", with the understanding that the word they supplied would not be the last in the sentence) confirmed that the closed-class context was much more predictive. Participants provided words of the same form class as the target most of the time for both cases, but were much more likely to provide the target given the closed-class context than the open-class context.

Shillcock & Bard's result is consistent with the constraint-based view that top-down information sources are integrated early in processing when they are sufficiently predictive. In the current experiment, we tested the hypothesis that even form class expectations for open-class words could constrain word recognition given a context with sufficient predictive power.

The Experiment

We hypothesized that form class could be sufficiently predictive to constrain initial activation if it were combined with strong visual and pragmatic expectations. For example, if there are four objects on a table – a brown purse, a purple book, a red ashtray, and a blue pen – and we ask you to pick one up, you would have strong expectations about how specific we would be in making reference to an item. For example, if we wanted the purse, you would expect to be asked, "pick up the purse" rather than "pick up the brown purse." Because of such conversational pragmatics (Grice, 1975), we would not expect subjects to experience strong competition between "purple" and "purse" as they hear "pur—," since if we wanted the book, we would ask for "the book," not "the purple book." But if there were brown and red purses, and purple and green books, given "pick up the pur—" we would expect little competition from *purse* – subjects would have a strong expectation to hear an adjective in this case.

Constructing such an experiment with real words poses significant problems. While there are many examples of cross-form class competitors in English, there are relatively few that are highly imageable and thus appropriate for our pragmatic manipulation. Even among these few, there is high variability in factors such as frequency and word length (e.g., purple-purse, dotted-dog, tan-tambourine, rough-rum).

Therefore, we extended an artificial lexicon paradigm that we previously developed to study the lexical neighborhoods of spoken words (Magnuson, Dahan, Allopenna, Tanenhaus & Aslin, 1998). An

Table 1: The artificial lexicon.

NOUN (shape)		ADJ (texture)	
1	pibo	pibΛ	1
2	pibe		
3	bupo	bupΛ	2
		bupe	3

		kagu	8
8	ga ¹ ku	ga ¹ kæ	9
9	ga ¹ ka ¹		

artificial lexicon allows precise control over such dimensions as phonological similarity and frequency of occurrence, as well as visual aspects of stimuli.

We created a lexicon of nouns (referring to novel shapes) and adjectives (referring to textures). The lexicon (shown in Table 1) contained phonemic cohorts (e.g., /pibo/ and /pibΛ/) in different syntactic categories (e.g., /pibo/ was a noun and /pibΛ/ was an adjective) or the same category (e.g., another noun was /pibe/). Thus, the artificial lexicon allowed us to compare phonological competitors in same or different form classes with similarity precisely controlled. (Note that there are even fewer examples of real words with comparable phonological competitors in the same form class and another, and the possible sets are quite heterogeneous, e.g.: purple-purse-person, tattered-tan-tambourine.)

Participants learned the lexicon over two days of training. Instructions were given in an English context, with English word order (e.g., "click on the /pibΛ/ [adj] /tedu/ [noun]"). We created conditions in which the visual context provided strong syntactic expectations by constructing contexts in which adjectives were required (e.g., two examples of the shape associated with /pibo/, but with two different textures) or infelicitous (e.g., two different shapes, making the adjective superfluous, even if the shapes have different textures). If syntactic expectations in conjunction with pragmatic constraints embodied in the visual display can constrain word recognition early in processing, we should observe competition effects only between cohorts from the same syntactic form class.

Methods

Participants

Eight native speakers of English who reported normal or corrected-to-normal vision and normal hearing were paid for their participation. Participants attended sessions on two consecutive days.

Figure 1: The 9 shapes and 9 textures.

Materials

The linguistic materials consisted of the 18 artificial words (9 nouns, referring to shapes, and 9 adjectives referring to textures) shown in Table 1. The auditory stimuli were produced by a male native speaker of English in a sentence context (e.g., "Click on the /bupetedu/"). The stimuli were recorded using a Kay Lab CSL 4000 with 16 bit resolution and a sampling rate of 22.025 kHz. The mean duration of the "Click on the..." portion of the instruction was 475 ms for adjective instructions, and 402 ms for noun instructions. For adjective instructions, mean adjective duration was 487 ms, and mean noun duration was 682 ms. For noun instructions, mean noun duration was 558 ms.

We examined the neighborhoods our artificial words would fall into were they real words of English; none would be in a dense English neighborhood (9 had 0 neighbors, and 7 had 1 neighbor). (See Magnuson [2001] for evidence that artificial and native lexicons do not interact, even when artificial items are constructed to be maximally similar to real words.) The visual materials consisted of unfamiliar shapes generated by randomly filling 18 contiguous cells in a 6x6 grid. We selected a set of 9 subjectively dissimilar shapes. These shapes provided referents for the nouns. In addition, 9 textures were selected from among the set distributed with Microsoft PhotoDraw. Figure 1 shows each of the 9 shapes, with a different one of the 9 textures applied to each (note that picture quality was substantially higher on the computer display). Names were randomly mapped to shapes and textures for each participant.

Eye tracking

During the tests (see Procedure), eye movements were monitored using a SensoriMotoric Instruments (SMI) EyeLink eye tracker, which provided a record of point-of-gaze in screen coordinates at a sampling rate of 250 hz. Saccades and fixations were coded from the point-of-gaze data using SMI's software.

Eye movements were used because they are closely time-locked to speech in a properly constrained task. Tanenhaus, Spivey-Knowlton, Eberhard & Sedivy (1995) found time locked fixations when subjects followed spoken instructions to perform a visually-guided task (e.g., "pick up the candle"). Because the subject must foveate the target item in order to efficiently follow the instruction, there is a functional link between the speech stimulus and dependent measure. This link avoids the pitfalls of interpreting eye movements described by Viviani (1990).

Alloppenna, Magnuson & Tanenhaus (1998) extended this work to a time-course issue in spoken word recognition. Whereas studies using more conventional tasks had failed to find evidence for the activation of rhymes during lexical competition, eye tracking proved sensitive enough to detect the robust (if relatively weak) rhyme activation predicted by various models (e.g., Luce & Pisoni, 1998; McClelland & Elman, 1986). Dahan, Magnuson & Tanenhaus (2001) applied the approach to a debate regarding frequency effects in spoken word recognition. Competing theories made conflicting predictions at the level of time course; for example, some argued it kicked in as a late bias (Connine, Blasko & Titone, 1993). Dahan et al.'s eye tracking measures demonstrated that frequency has a continuous but gradual influence from the earliest moments of processing, leading to the appearance of a late locus in less sensitive paradigms.

The eye tracking paradigm imposes different constraints than more conventional paradigms, such as lexical decision. In a conventional task, the stimuli are typically decontextualized; there is nothing about the task that predicts what word one might hear next. In the eye tracking paradigm, the stimuli are presented in the context of a display of items. While this allows more naturalistic tasks, it might also allow strategic processing. For example, participants might activate lexical representations in response to the visual display prior to any bottom up information, or the displayed set of items might provide a verification set to guide recognition. There is no evidence for lexical activation prior to the bottom-up signal; fixation proportions map precisely onto emerging phonetic similarity over time. We have also found that recognition in this paradigm is not based on lexical activations constrained to the displayed items: artificial lexical items (Magnuson, Tanenhaus, Aslin & Dahan, 1999, in preparation) and real words (Magnuson, 2001) in dense neighborhoods (i.e., with many or very frequent neighbors) are recognized more slowly than words from sparser neighborhoods, even when the neighbors are not displayed. This suggests the representations of the neighbors were activated and competed for recognition.

In summary, eye movements provide an extremely sensitive time course measure of lexical activation and competition. We need just such a measure to resolve the time course debate we are concerned with here: when

are top-down and bottom-up information integrated during spoken language understanding?

Procedure

Participants were trained and tested in sessions on two consecutive days. Each session lasted between 90 and 120 minutes. On day 1, participants were trained first on the nouns in a two-alternative forced choice (2AFC) task. On each trial, two shapes appeared (both with solid black texture) and the participant heard an instruction to click on one (e.g., "click on the bupo"). The auditory stimuli were presented binaurally through headphones (Sennheiser HD-570) using standard Macintosh Power PC digital-to-analog devices.

When the subject clicked on an item, one item disappeared, leaving the correct one, and its name was repeated. There were 14 repetitions of each item, split into 3 blocks of 48 trials. Items were not repeated on consecutive trials, and were ordered such that every item was repeated 7 times every 72 trials. Following the 2AFC blocks, noun training continued with 3 blocks of 4AFC, with identical ordering constraints and numbers of trials. Each shape appeared equally often as a distractor.

Adjective training then began. First, participants saw two exemplars of one shape, with different textures. They heard an instruction, such as "click on the bupe pibo". Since they already knew that, e.g., "pibo" referred to one of the shapes, participants found it transparent that "bupe" referred to one of the textures. As in the noun training, after they clicked on one item, the incorrect one disappeared and the full name was repeated. Each adjective and each noun was a target in 8 trials in each block; each adjective was randomly paired with 8 different nouns in each block. After three 48-trial 2AFC blocks, there were three 4AFC blocks, with four exemplars of the same shape with four different textures. These were followed by three more blocks of 4AFC, but with two exemplars each of two shapes, each with a different texture (requiring participants to recognize both the adjective and noun).

After this, a more complex training regime began. On some trials, four different shapes appeared. On others, two pairs of shapes appeared. On every trial, each shape had a different texture. On trials with two pairs of shapes, an adjective was required to make unambiguous reference, and the full referent was specified on such trials (e.g., "click on the bupe pibo"). On trials with four different shapes, the adjective was not required – each item could be identified unambiguously by the name of the shape, and so only the noun was specified in the instruction (e.g., "click on the pibo"). Using the adjective would be infelicitous, on Grice's (1975) maxim of quantity (one should not over-specify, which is the observed tendency in natural conversation). Each adjective was repeated 8 times in every block of 144 trials, paired each time with a different, randomly selected noun. Each noun was

repeated as the target item 8 times in the 4-noun trials. Trials were presented in blocks of 48. Participants completed 3 blocks of this mixed training on Day 1. On Day 2, they completed 12 more, which comprised the entire training phase on Day 2.

After each 48-trial block, the participant saw a summary of his or her accuracy in that block. To motivate participants, we told them that each training segment would continue until they reached 100% accuracy. Typically, we moved to each successive training phase after the number of blocks listed above for each segment, except in a few rare cases where participants were below 90% accuracy after the specified number of blocks, in which case training continued for another 1-2 blocks.

Each day ended with a 4AFC test with no feedback. We tracked participants' eye movements during the test. There were six basic conditions in the test. In the *noun baseline condition*, there were four different shapes, and no shape's or texture's name was a competitor of the target noun. In the *noun plus noun cohort condition*, there were four shapes, and one of them was a cohort to the target (e.g., the target might be /pibo/, and /pibe/ would also be displayed), but no shape had the target's adjective cohort texture applied (e.g., no shape would have the /piba/ texture). In the *noun plus adjective cohort condition*, four different shapes were displayed. The noun cohort was not displayed, but the adjective cohort was (e.g., a distractor might be /piba tedu/). In these conditions, the instruction would only refer to the noun (e.g., "click on the pibo").

In the other three conditions, two exemplars of two different shapes were displayed, requiring the adjective to be used in the instruction. In the *adjective baseline condition*, none of the distractor textures were cohorts of the target, and neither were any of the nouns. In the *adjective plus adjective cohort condition*, one of the non-target textures was a cohort to the target (e.g., the target might be /tedi dotu/, and one non-target might be /tede bupo/), but no noun cohorts of the target would be displayed. In the *adjective plus noun cohort condition*, none of the distractors would have textures that were cohorts to the target texture, but a noun cohort would be displayed (e.g., given /tedi dotu/ as the target, /bupe tedu/ might be included).

The following scheme was used to ensure that each adjective and target appeared 9 times as targets in the test. Note that nouns and adjectives either had one competitor in each form class, or two in the opposite form class. Nouns with noun cohorts appeared in six *noun baseline* trials, two *noun plus noun cohort* trials, and once in the *noun plus adjective cohort condition*. Nouns with two adjective cohorts appeared in 7 *noun baseline* trials, 0 *noun cohort* trials, and two *noun plus adjective cohort* trials. The same pattern was used with adjective conditions, giving a total of 162 test trials.

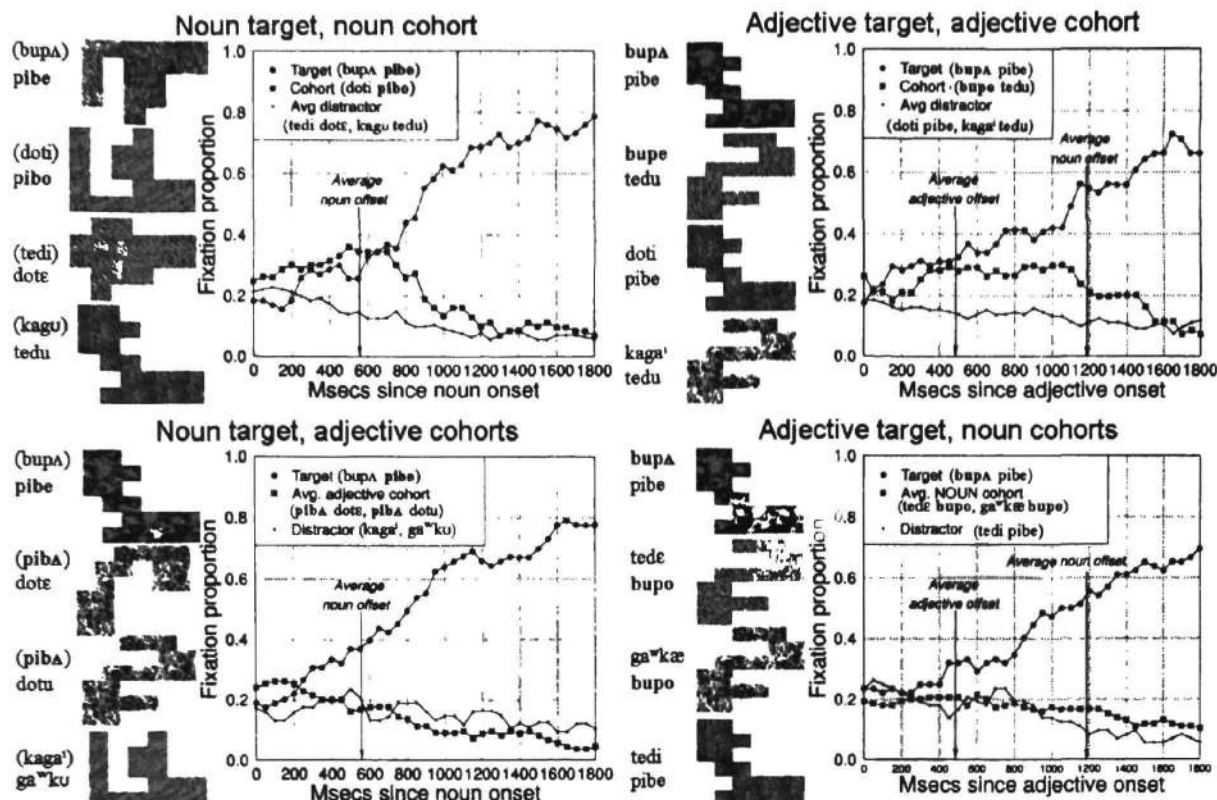

Figure 2: Results from the 4 critical conditions. The top panels show competition between within-class cohorts. The bottom panels show the failure to find competition for cohorts from different form classes.

Results

Participants attained high accuracy quickly (two failed to reach ceiling levels of accuracy, performing at less than 90% correct on the test on Day 2, and their data was excluded from the analyses). Mean accuracy on nouns and adjectives was 96% at the end of Day 1, and 98% at the end of Day 2. The results from the test on Day 2 are shown in Figure 2. Examples of possible stimulus items are shown to the left of each panel (these would be arranged around the central fixation cross in an actual experimental display). Note that in the cross-form class conditions (*noun with adjective cohorts* and *adjective with noun cohorts*) there were two cohorts in the display. This was necessary in the case of the *adjective plus noun cohort condition*; in order for the display to demand that an adjective be used, two exemplars of two different shapes had to be displayed. To make the *noun plus adjective cohort condition* comparable, two items were displayed with textures whose names were cohorts to the noun target.

The results show strong, immediate effects of the form-class constraints on lexical access. Compare the upper and lower panels of Figure 2. While strong cohort effects are apparent in the upper panels (the within-form class competitor conditions), there is no evidence for cohort effects in the lower panels (between-form

class conditions). Analyses of variance on mean fixation proportion in the noun conditions over the window from 200 ms (where we first expect to see signal-driven fixations, since it takes 150 – 180 ms to plan and launch saccades in much simpler tasks) to 1400 ms (where the target proportions asymptote) confirm the trends. There was a reliably greater proportion of fixations to the cohort than to the distractors in the *noun plus noun cohort condition* (cohort=.25, mean distractor=.12; $F(1, 11)=10.16$, $p=.009$), but not in the *noun plus adjective cohort condition* (cohort=.15, mean distractor=.15). The same was true for the adjective conditions, over the window from 200 to 1800 (the window was extended because of the longer lag prior to disambiguation). There were reliably more fixations to the cohort in the *adjective plus adjective cohort condition* (cohort=.22, mean distractor=.15; $F(1,11)=7.2$, $p=.02$), but not in the *adjective plus noun cohort condition* (cohort=.16, mean distractor=.15, $p=.59$).

Discussion

The results demonstrate that higher-level linguistic constraints (in this case, syntactic expectations based on a visually-defined referential context) influence even the earliest moments of lexical access when the constraints are highly-predictive. Phonemically similar

items competed only when they were from the same form class. This suggests, contra strong modularity (e.g., Fodor, 1983), that lexical activation can be constrained given a highly informative context.

In future research, it will be important to establish the limits of such effects. It may be the case that form class constraints would be weaker were there more members of each form class (as predicted by the argument that a noun or verb expectation in English is an extremely weak constraint). We are currently exploring this possibility with an expanded lexicon.

It is possible that visual/pragmatic constraints swamp lexical activation, and turn the display into a verification set. To eliminate this possibility, we will use a neighborhood density manipulation. We should find faster increases in target fixations for items in sparse neighborhoods *in addition* to the form class/pragmatic effects observed here.

The timing of these sorts of effects will be informative about how different classes of constraints are integrated in real-time spoken word recognition. The current results provide a starting point for further explorations while demonstrating that the artificial lexicon paradigm can be adapted to a wide range of microstructural issues in spoken word recognition. Moreover, they suggest that the failure to find immediate effects in earlier studies does not reflect an architectural property of the word recognition system (i.e., encapsulation), but rather reflects the pattern predicted by constraint-based models when contextual constraints are only weakly predictive.

Abstract

Linguistic labels, information about category memberships, have been found to be more important than perceptual information in guiding young children's inferences about animal kinds. However, perceptual information of static shape cues has often been stressed. A recent study has shown that young children tended to use dynamic perceptual cues, such as motion, more often than static shape cues to make categorical judgments. The overriding effects of linguistic labels over perceptual information in young children's inferences need to be re-examined. This paper was an attempt to examine how 3-year-old children use category labels and motion cues to draw inferences about animal kinds. Data showed that preschool children tended to use motion more often than labels when confronted with a choice between labels and motion. This provides support for our view that the role of category labels in young children's categorical judgments is not as important as what has been suggested in previous studies.

Introduction

The Importance of Category Labels

The importance of linguistic information in preschool children's inductive inferences about animal kinds has well been demonstrated in a series of studies by Gelman and her colleagues (e.g., Gelman & Markman, 1986, 1987; Gelman & Coley, 1990). In their studies, the extent to which children use category labels and perceptual appearance was examined. For instance, 2½ years old children were found to be more likely to assign a property, e.g., "lives in a nest", from a bluebird to an atypical bird, dodo, which looked different from the target but shared the same label "bird" than to a dinosaur which looked similar to the bluebird but carried a different label "dinosaur" (Gelman and Coley, 1990). However, when the stimuli were not labeled,

they tended to draw inferences based more on perceptual similarity than on the similarity of verbal labels. The young children were able to go beyond perceptual appearance and use linguistic labels to draw inferences, suggesting that linguistic information is more powerful than perceptual information for preschoolers to draw accurate categorical judgments. As Gelman and Coley (1990) stated that for young children "language conveys important information beyond that which meets the eye" (p.804).

Despite of this, the role of category labels remains to be determined as perceptual characteristics have generally been taken as static perceptual cues in Gelman et al.'s studies. Perceptual cues should also include dynamic properties, such as motion.

The Importance of Motion Information

In a recent study by Mak and Vera (1999), 4 and 7-year-old children have been found to categorize animals based more on motion similarity than on static shape similarity. For instance, they were more likely to categorize, for example, a donkey with an antelope than with a horse when the antelope and the donkey were shown to jump in the same manner even though the donkey looked more similar to the horse than to the antelope. The children tended to infer that the donkey shared the same property of "having poor vision" that was ascribed to the antelope rather than the property of "having good vision" ascribed to the horse. The role of motion information has been stressed.

As such, this paper tried to look further into the role of category labels and include motion information to study young children's inductive inferences about animal kinds. We will argue that the effectiveness of verbal labels is not as important as Gelman et al. have suggested.

Effectiveness of Category Labels?

Doubts have been raised about the significance of verbal labels in guiding children's categorical judgments. Although Gelman and Coley's (1990) studies found that young children were ready to draw inferences about animals based more on label similarity than on static shape similarity, their use of linguistic information seems to rely on the correspondence between the label and the perceptual information of the animal stimuli. If children find the labels are not congruent with the animal stimuli, they would not use the linguistic information. They would do so only when they believe that the labels and the stimuli match with one another. This has been illustrated in some of Gelman et al.'s studies.

For instance, Davidson and Gelman (1990) found that young children did not use familiar verbal labels to draw inferences about novel animal categories. In this study, 4- and 5-year-old children were tested with some imaginary animals; in one of the experimental conditions, familiar category labels (e.g., "cow" and "deer") were used. Results, which were different from those in Gelman and Coley's (1990) study, showed the preschool children tended not to draw inferences based more on label similarity than on perceptual similarity. This might be due to the fact that the children did not find the labels "cow" and "deer" congruent with the imaginary stimuli and therefore did not make judgments based on the labels.

Even when novel linguistic labels (e.g., "zav" and "traw") were used, the children did not use the novel labels and were more likely to use labels than perceptual appearance to draw inferences. The children, in this instance, might not be able to relate the novel labels to the imaginary animals; confronted with a choice between perceptual and linguistic information, they opted for static perceptual cues.

Therefore, if children find that the familiar labels and the animal stimuli do not match with one another, they would not use category labels. Only when children believe that the labels go well with the stimuli do they begin to find the linguistic information useful. Here are some more examples.

In Gelman and Markman's (1987) study, familiar animal categories (e.g., "cat" and "skunk") were used. Three- and 4-year-old children were found to be more likely to assign a property, "can see in the dark", from a target cat to another cat (which was shown in different coloring and posture) than to a skunk (which looked similar to the target cat) when the animal stimuli were labeled accordingly. However, the children also succeeded in doing so even when verbal labels were not provided. A follow-up study showed that children were able to determine the categorical memberships of the stimuli perceptually when the stimuli were not labeled. The animal stimuli seemed to be too familiar to the young children that they could make use of the subtle

Table 1

perceptual cues to draw accurate inferences and did not need to rely on the linguistic information (Gelman & Markman, 1987). Gelman and Markman (1987) unexpectedly found that familiar linguistic labels could not help the 3- and 4-year-olds. Only when 2½-year-old children were tested did they begin to find that verbal labels could help young children to draw inferences about familiar animals (e.g., "bird" and "dinosaur"). This may be due to the fact that the 2½-year-olds were somewhat but not completely familiar with the animal stimuli. They were not able to use the subtle perceptual cues to determine the category memberships of the stimuli and needed to rely on the category labels provided to draw accurate inferences.

This may also be true in the 3- and 4-year-olds in Gelman and Markman's (1986) study who were found to be guided by the similarity and dissimilarity of linguistic labels in drawing inferences about familiar animals (e.g., "bat", "bird", "dolphin", "fish"). In the experiment, young children were shown, for example, a "bird" set which included two target animals, a flamingo and a bat (which looked very different from one another, and a test animals), a blackbird (which looked more like the bat than the flamingo). In the conflict condition where the flamingo and the blackbird were labeled a "bird" and the bat a "bat", the children were more likely to categorize the blackbird with the flamingo than with the bat even though the blackbird looked more similar to the bat than to the flamingo. However, in the no-conflict condition where the bat and the blackbird were labeled a "bat" and the flamingo a "bird", the children tended to categorize the blackbird and the bat together. In other words, the children tended to make categorical judgments based more on linguistic similarity than on perceptual similarity. They were more likely to categorize the blackbird and the flamingo together when they shared the same label "bird" than when the blackbird was labeled a "bat" instead of a "bird", suggesting that the young children were not so familiar with the animal categories, birds and bats, that they were willing to accept the names, "bird" and "bat", to be used to label the blackbird. If the stimuli were completely familiar to them, they would not have been guided by the similarity and dissimilarity of verbal labels, like the 4 and 5-year-olds in Gelman and Markman's (1987) later study.

To summarize, the effectiveness of familiar linguistic labels in guiding young children's inferences is rather limited, which relies on two major factors – whether children find the familiar linguistic labels and the perceptual information of the animal stimuli match with one another and their familiarity with the stimuli. Only when children believe that the linguistic labels are not in conflict with the stimuli and they are somewhat but not completely familiar with the stimuli does the linguistic information become useful. Otherwise, linguistic labels cannot help children to draw accurate

Animation items, category labels and target properties used.

Pair	Test displays			Target displays			Property
	Animal	Motion	Label	Animal	Motion Same/Different	Label Same/Different	
1	Horse	Walk	"Horse"	Donkey	Walk/Jump	"Horse"/"Donkey"	Good vision
2	Quail	Walk	"Quail"	Sparrow	Walk/Hop	"Quail"/"Sparrow"	Good hearing

inferences. The effectiveness of linguistic labels in guiding children's inferences is not as significant as Gelman et al. have proposed.

The Present Study

In view of the above, it seems to be reasonable to believe that perceptual information, including both static and motion cues, may not be relatively unimportant in comparison to familiar verbal labels. It is evident that young children not only rely on linguistic labels but also use perceptual characteristics to draw inferences about animal kinds. In this paper, we would like to like to examine to what extent young children use familiar linguistic labels and motion cues to draw inferences.

It is postulated that young children, such as 3-year-old children (who have been found to be ready to draw inferences based on the similarity and dissimilarity of familiar linguistic labels), would use both verbal labels and motion cues to draw inferences about animals. However, when confronted with a choice between labels and motion, they would tend to use motion information more often than linguistic information.

Method

Design

To examine the extent to which 3-year-olds use familiar linguistic labels and motion cues to draw inferences about animal kinds, an inductive methodology used in previous studies (Gelman & Markman, 1986, 1987; Gelman & Coley, 1990; Mak & Vera, 1999) was adopted. Here, young children were required to consider a pair of animals, a target and a test. They were taught a new property about the target animal and were asked whether the target property was true for the test animal.

The independent variable was three *motion/label* conditions: *label and motion*, *label only* and *motion only*. The dependent measure was children's responses on the inference questions: whether they would generalize the target properties to the test animals.

Participants

Two hundred and twenty 3-year-old children from three kindergartens in Hong Kong participated: 110 girls and 110 boys, ranging in age from 3 years to 3 years 11 months with a mean age of 3 years 7 months.

Stimuli

There were two pairs of animal stimuli: (1) a donkey and a horse, and (2) a sparrow and a quail. Each pair consisted of animals with similar appearance and two series of animations: same and different movement. The movement of the animals in the animations was slightly slower than the corresponding real motion, but they all moved in the same speed. Also, all the stimuli were drawn in the same brown color with black outline. The drawings of the animal stimuli used for the animations are shown in Fig. 1, and the details of the animation items are shown in Table 1.

Figure 1
The drawings of animal stimuli used for the animation items.

Control Studies

Property Controls

Some control studies were run to make certain if 3-year-old children have any biases in assigning the target properties to the test animals which were shown to be static or with certain movement and linguistic labels. In these controls, children were shown the test animals alone (i.e., the horse and the quail) one at a time and were asked if the target properties (i.e., "good vision" and "good hearing") were true for the horse and the quail respectively. Results are summarized in Table 2.

Table 2
Percentages of "yes" responses for 3-year-old children in the Property Controls.

Control Condition	Percentage
Static	52.5
Label only	57.5
Motion only	52.5
Label and Motion	55

n=20 (half boys and half girls)

Data showed that 3-year-olds performed at about chance level in saying that the target properties were true for the test animals, showing no biases in giving "yes" responses to the test animals.

Static Controls

Two animals of similar appearance were adopted. To confirm if young children were ready to draw inferences based on the static perceptual similarity of the animal stimuli, a static control study was also conducted. In this control, 3-year-old children (10 boys and 10 girls) were presented with two sets of animals but one set at a time without motion. Children were tested to see if they would generalize the target properties to the test animals based on static shape information alone. Data showed that the young children were willing to do so 85% of the time, which was significantly above chance level, $p < .0005$ (1-tailed), suggesting that 3-year-olds were ready to draw inferences based on the static shape similarity of the animal stimuli.

Procedure

This was a between-subject design, so that a child (e.g., being assigned to the *Same-Label* and *Different-Movement* condition) was tested with two pairs of animals. One was the *donkey/horse* pair; both were labeled a "horse" but were shown to move in different manners (i.e., the donkey jumped and the horse walked). The other one was the *sparrow/quail* pair; both shared the same name "quail" but were shown to move differently (i.e., the sparrow hopped and the quail walked). The presentation order of the two pairs was counterbalanced across participants. Each child was tested individually. Throughout the experiment, instructions were given in Cantonese, the major Chinese dialect used in Hong Kong. Each child was tested individually.

Children were shown two pairs of animals, one pair at a time. They were first taught a new property about the target animal in each pair and were then asked to infer whether the target property applied to the test animal. The animal stimuli were labeled according to the label conditions. Taking the *donkey/horse* pair in

the *Same (Different) Label* conditions as an example, the experimenters first pointed to the donkey and said, "See this *horse (donkey)*. This *horse (donkey)* has *good vision*; it can see things clearly at a great distance." The experimenter then pointed to the horse and said, "See this *horse (horse)*. Does this *horse (horse)* have *good vision*, like this *horse (donkey)* (referring to the donkey) that can see things clearly at a great distance? Or, this *horse (horse)*, unlike this *horse (donkey)*, does not have *good vision*?"

At the end of the experiment, children in the *Same Label* groups, who were given somewhat misleading labels for the target animals, were shown the stimuli again and were told that the experimenters had made a mistake in saying that the donkey (sparrow) was a *horse (quail)*. The experimenters further explained to the children that its proper name should be *donkey (sparrow)* instead of *horse (quail)*.

Results

Children's responses on the inference questions were coded as 1 when they said "yes" (i.e., generalizing the target properties to the test animals) and 0 when they said "no" (i.e., not generalizing the target properties to the test animals). These scores were summed within participants, and the score for each participant ranged from 0 to 2. For each condition, a one-sample *t*-test was conducted to examine if children performed significantly above or below 50% chance level. Results are summarized in Table 3.

Motion only condition

Data in these conditions clearly show that 3-year-old children were ready to draw inferences about the animal stimuli based on the similarity and dissimilarity of the motion information. When two animals with similar appearance were shown to move in the same manner, the young children tended to infer that the test animals shared the same property ascribed to the target animals (87.5% of the time, significantly above chance level); when the two animals moved differently, the children tended not to do so (20% of the time, significantly below chance).

Table 3
Percentages of "yes" responses for 3-year-old children in *Label only*, *Motion only* and *Label and Motion* conditions.

Condition		Percentage	
Motion only	Same	87.5	***
	Different	20	++
Label only	Same	90	***
	Different	15	+++
Label and Motion	Same Label/Different Motion	10	+++
	Different Label/Same Motion	82.5	***

n=20 (half boys and half girls)

*** above chance, $P < .0005$, one-tailed

+++ below chance, $P < .0005$, one-tailed

++ below chance, $P < .005$, one-tailed

Label only condition

Three-year-old children were also found to draw inferences based on the similarity and dissimilarity of the linguistic labels provided in the experiment. When two animals with similar appearance shared the same name, the 3-year-olds tended to agree that the target properties were also true for the test animals (90% of the time, significantly above chance). The children did not do so (15% of the time, significantly below chance) when the two animals were labeled with different names.

Label and Motion condition

In these conditions, label similarity and motion similarity were in contrast with one another. Results indicate that the 3-year-olds were more likely to draw inferences about the animal stimuli based on motion information than on linguistic information. When two animals moved in the same manner, the children tended to draw inferences 82.5% of the time (significantly above 50% chance level) even though the stimuli were labeled with different names; when two animals moved in different manners, they tended to draw inferences 20% of the time (significantly below chance) although the animal stimuli shared the same name.

In order to have a clearer picture of how children changed their choices between linguistic and motion information, 3-year-old children's responses in *Label only* and *Label and Motion* conditions are shown in Figure 2.

Figure 2
Percentages of "yes" responses for 3-year-old children in *Label only* and *Label and Motion* conditions.

This figure shows that 3-year-olds tended to shift their choices from linguistic labels to motion when contrasting motion information was introduced in addition to the linguistic information. Children drew inferences 90% of the time from a target to a test animal when two animal stimuli shared the same name in the *Label only* condition, whereas they made inferences only 10% of the time when additional different movement patterns were introduced to the stimuli in the *Label and Motion* condition. Moreover, children drew

inferences 15% of the time when two stimuli were labeled with different names in the *Label only* condition, while they gave "yes" responses 82.5% of the time when the stimuli were shown to move in the same manner even though they were labeled with different names in the *Label and Motion* condition.

However, 3-year-olds did not change much about their choice of motion information when additional contrasting label information was introduced. Children's responses in *Motion only* and *Label and Motion* conditions are shown in Figure 3.

Figure 3
Percentages of "yes" responses for 3-year-old children in *Motion only* and *Label and Motion* conditions

This figure shows that children drew inferences 87.5% of the time when two animals moved in the same manner in the *Motion only* condition and did likewise 82.5% of the time even when different labels were ascribed to the stimuli in the *Label and Motion* condition. Moreover, when two animals moved in different manners in the *Motion only* condition, children made inferences only 20% of the time, and they drew inference 10% of the time even though the same label was ascribed to the stimuli in the *Label and Motion* condition.

Discussion

The current findings provide support for our hypothesis that linguistic information may not be relatively more important than perceptual information, including both static and dynamic characteristics, in guiding young children's inferences about animal kinds. Data show that 3-year-old children were ready to use both category labels and motion information to draw inferences. However, having to make a choice between labels and motion, children tended to use motion more often than familiar category labels.

Also, this seems to provide support our view that the effectiveness of category labels in guiding young children's inferences about animals may be rather limited. The importance of linguistic labels that has been suggested by previous studies need to be rethought.

Although to what extent children use category labels and motion was compared in this study, we are not suggesting that linguistic and perceptual information play distinct roles in young children's inferences (for this argument, see also Gelman & Medin, 1993; Jones & Smith, 1993). Evidence has shown that children use both linguistic and perceptual (including static and dynamic) information to draw inferences. However, how static shape cues, motion and linguistic labels interact to guide children's inferences remains to be determined in future studies.

Abstract

Many applications accessible through the web suffer from a noticeable lack of support in adapting the information presentation to users. The way users learn differs from an individual to another, if not for the same individual from an application to another one. These individual differences affect the learning style of users. They are classified into 3 categories which are: *affective*, *cognitive* and *physiologic styles*. There is little research to examine how to design adaptive systems based on user's cognitive styles. In this paper, we are focusing on user cognitive styles definition and suggest a technique in the design of an adaptive hypermedia system. We investigate the selection of the output modality that best tailor the user profile.

In section 1 we introduce the problematic of learning from net-structured knowledge then we define the cognitive styles. In section 2, we present the main cognitive styles which are the most mentioned in literature. The taxonomy of these cognitive styles and techniques to assess them are detailed in section 3. In the last section, we present the structure of our site and model. We investigate the relationship between the cognitive style and the filtering process of the outcome modalities. For the development of the system, we have chosen the two technologies : XML and ASP.

Introduction

In e-learning systems, the user is confronted to lessons, exercises, games... which, on the one hand are relevant to his/her needs and preferences i.e. educational level, domain knowledge (expert or novice) but which, on the other hand, do not take into account his/her abilities for assimilation, memorization, etc. which are parts of the cognitive abilities (Lemaire, 1999). In some cases, the learner gives up the game or the exercise because of the frequent situations of defeats. In other cases, he/she tries hard to make his/her best in order to avoid these situations which overload his/her abilities. The aim of our project consists in developing an adaptive multimodal interfaces where individual cognitive styles are considered. Indeed, the adaptation process deals with the estimation of the document combination (in

other word, the multimodal interface) which is the most compatible with the cognitive profile.

In the following sections, we present our site then we define the term "cognitive styles", assess the main styles encountered in literature then discuss the taxonomy of ways employed to measure the cognitive style. Later in section 4, we describe the functionalities of our site and the model we adopted to establish the relationship between the cognitive style and the filtering process of the outcome modalities.

Our Site

In collaboration with the society SBT, we work on an interactive web site for a supervised cognitive training (www.happyneuron.com). During each training session (i.e. each connection), the user executes a set of exercises that the system suggests. Presented into a playful and cultural dimension, the exercises vary in difficulty's level, speed... in order to entertain the user (Habieb-Mammar et al, 2001).

A database stores normalized data (means and standard deviations) for each variant of exercise and family of population distinguishing gender, level of education and age (Tarpin-Bernard et al, 2001). The current statistics show that since the web site has been opened to the public, the number of performed exercises exceeds 400.000. Comparing the trainee's results and the normalized data we progressively build his/her cognitive profile. Thanks to it, the system advises the elderly user in the choice of exercises.

In this context, we built an evaluation module composed of ten precise exercises that allows to quickly build a cognitive profile. Then, this profile, which is quite stable, can be used in very different context. Our first purpose is to elaborate an adaptive multimedia course on the brain. Depending on one's profile, the lesson will be presented using the most adapted medias. Before describing the relationship between cognitive styles and interactive styles let start with the definition of these cognitive styles and the methods of their assessment.

What are Cognitive Styles?

Cognitive styles refer to a person's habitual, prevalent, or preferred mode of perceiving, memorizing, learning, judging, decision-making, problem-solving (Dufresne, 1997).

Individual differences about how people carry out tasks involving these functions may constitute a style if they appear to be: pervasive, which means that they emerge consistently in different contexts, independently of the particular features of situation; or stable, that is, they are always the same at different times.

They are one of the most stable user characteristics overtime (Dufresne, 1997). they are consistent across a variety of situations, as opposed to user knowledge or experience that are more specific and evolving. Many research have shown the importance of cognitive styles in the area of HCI and their implication in the interface design (Muytewijk et al, 1983).

Cognitive styles induce persons to adopt similar attitudes and behaviors in a variety of domains they concern (Daniels, 1996). Cognitive styles are important in determining the most effective interface for a particular category of user, especially in the formative stages of an interaction (Fowler et al, 1985).

They can be conceptualized as a cross-road of thinking, personality, and motivation. In fact they concern the kind of strategies which an individual tends to apply when he/she faces a situation or the preferred way of processing information.

The Main Cognitive Styles

Field Dependence

The first style we introduce is: field-independent style. People tend to have good analytical and cognitive restructuring skills. They will actively reorganize information according to contextual demands and impose structure when necessary according to their experience. They are likely to form a mental model of the situation before proceeding with their task. Field-independent people seem to follow more easily a restructuring approach and use internal referents in other situations (Antonietti et al, 2000).

Field-dependent people tend to adopt a passive approach in learning and problem solving. They prefer to be guided and to rely on external referents. Perception is dominated by the prevailing field.

When internal referents are less available, field dependent people are more likely to respond to the dominant properties of the field as given.

Lesser use of restructuring may handicap field dependent people in unstructured situations. field dependent people may need more explicit instructions in problem solving strategies or more exact definitions of performance outcome than field independent, who

may even perform better when allowed to develop their own strategies (Witkin et al, 1981).

However, the restructuring process occurs only when the field lacks organization. When the material to be learned is presented in an already organized form, so that structuring is not particularly called for, field dependent and field independent people are not likely to differ in their behavior and learning (Antonietti et al, 2000).

In general field independent subjects :

- Perceive objects as separate from the field;
- Can disembed relevant items from non-relevant items within the field;
- Provide structure when it is not inherent in the presented information;
- Reorganize information to provide a context for prior knowledge;
- Tend to be more efficient at retrieving items from memory.

Conversely, field dependent subjects:

- Rely on the surrounding perceptual field;
- Have difficulty attending to, extracting, and using non salient cues;
- Have difficulty providing structure to ambiguous information;
- Have difficulty restructuring new information and forging links with prior knowledge;
- Have difficulty retrieving information from long-term memory.

The test of field dependent-independent subjects is done through several exercises where individual are asked to remember shapes or other types of information whether they were presented in significant context (Fig. 1) or not (Fig. 2) (Tarpin-Bernard et al, 2001).

Figure 1: Significant context.

Figure 2: Non-significant context.

Impulsive reflective style

The impulsive subject tends to put forward the first idea that comes to him/her, whereas the reflective subject considers alternatives. This style is generally assessed by measuring differences in decision-making under conditions of uncertainty. Tasks used present several plausible choices, only one of which is correct:

- who responds quickly often errs;
- who pauses to reflect is more often correct.

Fig. 3 is an example of exercise where it is possible to identify one of the following categories:

- fast-responding/high-error (FH);
- fast responding/low-error (FL);
- slow-responding/high-error (SH);
- slow-responding/low-error (SL).

Figure 3 Exercise type for impulsive reflective identification.

Categorization style

Other individual differences consist in giving a number of objects and asking subjects to sort them into categories. Some individuals place objects into a wide number of small categories, so that each category contains only objects sharing a high number of similar features; other individuals place objects into a small number of wide categories which include items with

few common features. Other individuals may group objects into different categorization where the criteria are not only the width:

- *analytic-descriptive style* induces to include in the same category items showing surface physical-perceptual similarities;
- *conceptual-inferential style* induces to define categories on the basis of similarities in objects' functions;
- *thematic-relational style* induces to include in the same category disparate objects which have in common only the fact that they occur in the same action or situation.

Figure (Fig.4) shows an exercise where subjects are invited to sort objects into categories suggested by the supervisor. Firstly, the users select the category then they sort object into this category.

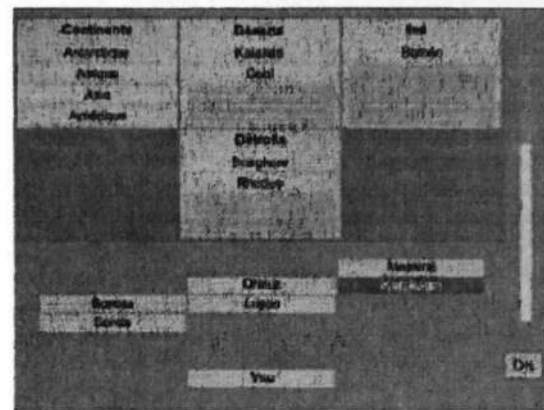

Figure 4 Exercise type for the category identification

Analytic-global style

The last style we consider is the analytic-global style which refer to either considering the details of a situation or the whole picture (Euzeby, 1999). Analytic individuals have a focused attention, an interest in operations and procedures or the 'proper' ways of doing things and prefer step-by-step schemes; their thinking is controlled and consciously directed. Global persons tend toward scanning, leading to form overall impressions, including entry of feelings into decisions; their organizational schemes involve random or multiple accessibility of components and varied associations between them.

Some tests in cognitive styles analysis (Riding and Rayner, 1998) allow to measure the analytic dimension by presenting items each comprising a simple geometrical shape and a complex figure and by asking to indicate whether or not the simple shape is contained in the complex figure.

How do we Assess Cognitive styles?

Three main kinds of data can be employed to measure cognitive styles: behavioral, self-report, and physiological (Antonietti & Giorgetti, 1998)

Behavioral data can be obtained by recording the final result of a given task or the procedure followed in performing the task. The task may consist in filling out a paper-and-pencil test or a sorting test, in carrying out trials by means of an experimental apparatus, or in interacting with the computer like during exercise running (Tarpin-Bernard et al., 2001). For an example, to assess whether a person is a visualizer or a verbalizer, it is possible to present him/her with tasks which can be performed through both visual and verbal strategies and to record the extent to which each of the two kinds of procedures has been followed.

Self-reports require that people evaluate themselves by describing by introspective manner the way in which they performed tasks, by checking personal habits or preferences, or by endorsing statements about what they think of themselves. This may be done, for example, by asking subjects to keep a diary of what occurred to them during a period of their life, by interviewing them, or by adopting questionnaires.

The following example is given by Antonietti (Antonietti & Giorgetti, 1998):

In order to understand how much an individual tends to visualize, he/she can be requested to keep a record of the times in which he/she has experienced imagery during the day. Information of this kind may be derived also through questionnaires in which people are asked to rate how frequently they create and process various kinds of mental images. These instruments incite subjects to consider their habitual modes of thinking as they emerge in the complete range of mental activities and to assess the occurrence of visual images in different tasks, domains, contexts, and so on.

Finally, some physiological measures can be interpreted as indices of particular cognitive preferences in processing stimuli. Indeed, Physiological measures observations have indicated that when someone is asked a question requiring a little thought the eyes make an initial movement to the left or right. Since it was argued that the right cerebral hemisphere is associated with the processing of visual information and that the spontaneous lateral eye movements are under the control of the counter-lateral hemisphere, it was claimed that the presentation of a visual-spatial question produces the activation of the right hemisphere and, consequently, left lateral eye movements. However, verbalizers should turn their eyes consistently to the right and visualizers to the left, whatever the kind of question. Thus, it has been suggested to use lateral eye movements as a criterion to assess the preference for either a visual or a verbal processing.

Relationship Between Cognitive Styles and Interaction Styles

The most important components of HappyNeuron's technology are structured as follows (Fig. 5) :

First stage: User's profile generation process (Tarpin-Bernard et al, 2001)

- Questionnaire;
- Exercises;
- Supervision process;
- Cognitive styles
- User profile;

Second stage: Adaptation process

- Compatibility matrix;
- User profile;
- XML (eXtensible Markup Language) documents (multimodal documents);
 - Text;
 - Image or graphics;
 - Sound;
 - Video.
- Stylesheet;

Figure 5: User profile generation and adaptation process

User's profile generation process

The user's profile generation process consists on the one hand in executing interactive exercises then constructing the user cognitive profile. On the other hand, it deals with other user's behavior such as the time to run an exercise, performance variations for the same exercise type, etc. This indicators are adjusted with each other and constitute the final user profile (Fig. 6).

Figure 6: The user's profile generation process

During each training session, the supervisor suggests a set of three or four exercises. The user can also select other exercises in the complete list. At any moment, the system gives users feedback about their progression and enables them to:

- check their performance by consulting the *profile performance page*,
- have a summary of the exercises they have already done,
- browse some documents (news, forums,...).

Thus, the main components of the output profile are:

- 1- Cognitive indicators dispatched into 5 sectors: *memory, attention, executive functions, language and visual and spatial capacities* [Tarpin-Bernard et al, 2001]. In total, 25 indicators have been determined, we can mention several of them as an illustration: cultural memory, old personal memory, recent memory (verbal, visual or musical), working memory and short term memory with the tree modalities, lexical spelling, categorization, comprehension, arithmetic, planning, reasoning, mental imagery, form recognition, etc ;
- 2- Behavioral indicators (time during exercise running, connection frequency, etc.);

- 3- Indicators revealing some characteristics of styles such as field dependent or independent.

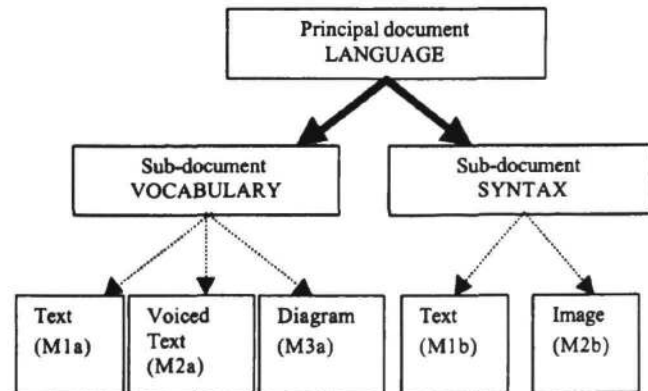

These indicators are affected with some weightings and contribute in the adaptation process. For example to determine whether the subject is field dependent or independent, we use the indicator which measures the difference in performance after running the same exercise with two different images (the first with significant context and the second with non-significant context) then we adjust it with other cognitive indicators such as recent memory (verbal, visual or musical) and comprehension.

Adaptive Process

As described in figure 5, the training process yields a user profile which constitutes the input data for the adaptation process. Indeed, this profile enables the selection of the outcomes style sheets. The multimodal document is defined into an XML document.

Prior to any process, each style sheet contains the layout of a complete page to be presented. For a specific subject, the final layout of this page is brought through the adaptive process. This page is the most compatible one to the user profile.

To illustrate the adaptive process, we give hereafter an example of a page to be presented dealing with the following subject : "The main parts of a language : the vocabulary and the syntax". In the XML document, the page falls under 2 elements. Each one could be presented according to different modalities. (Fig.7).

- Is composed of
-→ The possible modalities are

Figure 7: XML document structure

The problem is to find the "best" combination of modalities according to the willing of the designer and the abilities of the reader. According to the XML structure, the possible combinations are: (M1a, M1b), (M1a, M2b), (M2a, M3a, M1b), etc. Then, we can build

Metacat: A Self-Watching Cognitive Architecture for Analogy-Making

James B. Marshall (marshall@cs.pomona.edu)

Computer Science Program

Pomona College

610 N. College Ave.

Claremont, CA 91711 USA

Abstract

This paper describes Metacat, an extension of the Copycat analogy-making program. Metacat is able to monitor its own processing, allowing it to recognize, remember, and recall patterns that occur in its "train of thought" as it makes analogies. This gives the program a high degree of flexibility and self-control. The architecture of the program is described, along with a sample run illustrating the program's behavior.

Introduction

This paper describes Metacat, an extension of the Copycat analogy-making program originally developed by Hofstadter and Mitchell (Hofstadter, 1984; Mitchell, 1993). Copycat was developed as a model of the complex interplay between bottom-up and top-down perceptual processes in the mind, which together enable humans to perceive analogies between different situations in remarkably flexible ways. The program operates in an idealized microworld of analogy problems involving short strings of letters. Although the program understands only a limited set of concepts pertaining to its letter-string world, its "fluid" processing mechanisms give it considerable flexibility in recognizing and applying these concepts in many diverse situations.

The long-term goal of the Copycat line of research is to computationally model how high-level cognitive phenomena such as creativity, analogical perception, understanding, and self-awareness can arise out of a subcognitive substrate composed of a huge number of tiny, nondeterministic processes, each of which is far too small by itself to support such phenomena. Few people would suggest that individual neurons in the brain (or individual molecules) are "conscious" in anything like the normal sense in which humans experience consciousness. One is forced to accept the fact that self-awareness arises, somehow, out of nothing but billions of molecular chemical reactions and neuronal firings. How can individually meaningless physical events in a brain—even a huge number of them—ultimately give rise to meaningful awareness? Hofstadter has argued that two key ideas are of paramount importance (Hofstadter and FARG, 1995):

What seems to make brains conscious is *the special way they are organized*—in particular, the higher-level structures and mechanisms that come into being. I see two dimensions as being critical: (1) the fact that brains possess *concepts*, allowing complex representational structures to be built that automatically come with associative links to all sorts of prior experiences, and (2) the fact that brains can *self-monitor*, allowing a complex internal self-model to arise, allowing the system an enormous degree of self-control and open-endedness.

Work on Copycat explored the first idea through the development of a computer model of analogy-making in which the program's representation of concepts is intimately intertwined with its mechanisms for perceiving similarity between different idealized situations. Recent work has focused on the second idea by incorporating *self-watching* into the model—namely, the ability of a system to perceive and to explicitly characterize its own perceptual processes. The objective of this work has been to develop mechanisms that allow the program to monitor its own actions and to *make explicit* the ideas that come into play during the course of solving analogy problems. This can be thought of as adding a higher "cognitive" layer on top of the program's "subcognitive" layer, enabling the program to watch and remember what happens at its subcognitive level as perceptual structures are built, reconfigured, and destroyed. Humans are capable of paying attention to patterns in their own thinking in a similar fashion (see, for example, Chi *et al.*, 1994).

Self-watching in Copycat and Metacat

The Copycat architecture has been discussed at length elsewhere (Mitchell, 1993; Hofstadter and FARG, 1995), so details will be omitted here. Briefly, the program consists of a long-term memory of concepts about the letter-string world, called the *Slipnet*, together with a short-term memory for perceptual structures, called the *Workspace*. In the Workspace, small nondeterministic agents called *codelets* examine the letters of an analogy problem (" $abc \Rightarrow abd$; $mrrjjj \Rightarrow ?$ ", for example), and build

up structures around the letters representing a particular interpretation of the problem. The program's high-level behavior emerges in a bottom-up manner from the collective actions of many codelets working in parallel, in much the same way that an ant colony's high-level behavior emerges from the individual behaviors of the underlying ants, without any central executive directing the course of events.

Guiding the search for a mutually-consistent set of structures are concepts in the Slipnet, which become activated to different degrees depending on the activity in the Workspace. This activation may spread to neighboring concepts, and strongly influences codelet decisions, resulting in top-down pressure that guides the program in its search for a good interpretation of a problem.

The overall degree of Workspace organization is measured by a number called the *temperature*. Temperature not only reflects the state of the Workspace, it also continuously regulates the amount of randomness used by codelets in making decisions. At high temperatures, few Workspace structures exist, so decisions are made in a highly random manner, since not much is yet known about the problem. However, as relationships among the letters are noticed and structures are built, the temperature falls, and Copycat begins to gain "confidence" in its understanding of the situation. At lower temperatures, decisions are still probabilistic, but are much less random, being strongly biased by the estimated promise of newly emerging structures, all of which compete for attention by codelets. At very low temperatures, codelets pay attention to only the most promising structures, and decisions become largely deterministic. Thus the type of strategy used by the program to explore its search space ranges along a broad continuum, from being very diffuse and highly parallel at high temperatures to being very serial and focused at low temperatures.

To summarize, Copycat's search proceeds via a large number of fine-grained stochastic decisions, which depend on the temperature. These decisions may cause new structures to be built or existing structures to be destroyed, which changes the temperature and subsequently alters the course of structure building, forming a kind of feedback loop. Temperature thus serves as a very crude mechanism for self-watching in Copycat, since it allows the program to regulate its own behavior to a limited extent. That is, by tying the stochastic activity of codelets to the temperature, the program becomes sensitive to the consequences of its own actions, since the temperature reflects the result of these actions, albeit in a very coarse way (i.e., in the form of a single number).

This type of rudimentary self-watching, however, is quite primitive. Copycat can characterize patterns within its perceptual input (the letter strings), but is completely oblivious to patterns that arise in its

processing of that input. For example, when solving the problem " $abc \Rightarrow abd; xyz \Rightarrow ?$ ", Copycat usually attempts to take the successor of *z*, which is impossible in the program's microworld. It "hits a snag", and is forced to try something else. However, it often just tries the same thing again, over and over, sometimes as many as thirty or forty times before stumbling by chance on an alternative approach (such as the answer *xyd*). Unlike humans, the program is unable to recognize when it has fallen into a repetitive pattern of behavior. It has no memory of its actions over time, and thus cannot recognize when it has encountered the same situation in the past. As a result, Copycat lacks insight into how it arrives at its answers, and consequently cannot explain what makes one answer better or worse than another.

In contrast, Metacat is able to create much richer representations of the analogies it makes, enabling it to compare and contrast answers in an insightful way. This has involved incorporating an episodic memory into the original Copycat architecture, along with new mechanisms that allow the program to monitor itself, so that it can recognize, remember, and recall patterns that occur in its "train of thought" as it makes analogies.

To do this, Metacat creates an explicit sequential record of the most important processing events that occur during a run. This temporal record is examined by codelets for patterns—in the same way that Copycat's codelets examine letter-strings for patterns—and serves as the basis for constructing an abstract description of an answer in terms of the key concepts and events that led to its discovery. Furthermore, by monitoring its own processing in this way, Metacat can recognize when it has become "stuck in a rut", enabling the program to break out of the rut by focusing on ideas other than the ones that seem to be leading it nowhere.

The Architecture of Metacat

Metacat's architecture includes all of Copycat's architectural components, such as the Workspace and the Slipnet, as well as three new components: the *Episodic Memory*, the *Thespace*, and the *Temporal Trace*. When the program discovers a new answer, it pauses to display the answer along with the Workspace structures that gave rise to it. These structures represent a way of interpreting the problem that yields the answer just found. All of this information is then packaged together into an *answer description* and stored in the Episodic Memory, after which the program continues searching for alternative answers to the problem, instead of simply quitting. Gradually, over time, a series of answer descriptions accumulates in memory, each one containing much more information than just the answer string itself.

The most important structures stored in answer

descriptions are called *themes*, which represent the essential ideas underlying an answer. The collection of themes associated with an answer serves as the basis for comparing it to other answers stored in memory. Furthermore, Metacat may be reminded of other answers it has encountered in the past if the themes associated with a newly discovered answer, acting as a memory retrieval cue, are similar enough to those of a previously stored answer description. Thus an answer's themes act as an index under which it is stored and retrieved from memory.

Themes get created in Metacat's Thespace as codelets build structures around the letter-strings, and are composed of Slipnet concepts. For example, in the problem " $abc \Rightarrow abd$; $xyz \Rightarrow ?$ ", an *Alphabetic-Position: opposite* theme representing the idea of alphabetic-position symmetry between the letters *a* and *z* might get built if the program perceives these letters as playing analogous roles in their respective strings (an interpretation that may lead to the "mirror image" answer *wyz*).

In some ways, themes are like ordinary Workspace structures. They are not initially present in the Thespace; rather, they arise during the course of a run as the result of codelet activity occurring in the Workspace. In other ways, however, themes behave like Slipnet concepts. They can take on different levels of activation, reflecting the extent to which the ideas they represent are supported by structures in the Workspace. A theme's activation level decays over time, and is influenced by the activation levels of other themes. Like Slipnet concepts, themes can, under certain conditions, exert strong top-down pressure on perceptual activity in the Workspace. In fact, themes can assume both positive and negative levels of activation, ranging from -100 to $+100$. A positively-activated theme exerts "positive thematic pressure", encouraging the creation of Workspace structures that support the idea represented by the theme. A negatively-activated theme, on the other hand, exerts "negative thematic pressure", which discourages the creation of structures related to the theme, promoting instead the creation of alternative structures.

The Temporal Trace serves as the focal point for self-watching in Metacat. Like the Thespace, the Trace accumulates information over the course of a single run, and can be viewed as an extension of the Workspace. The Trace stores an explicit temporal record of the most important processing events that occur while the program works on an analogy problem. Examples of such events include recognizing some key idea pertaining to the problem (by noticing the strong activation of a theme or concept, for instance), hitting a snag, or discovering a new answer. Once processing events have been explicitly represented in the Trace as "reified" structures in their own right, they are subject to examination by codelets as well. Metacat thus uses a single set of

mechanisms for perceiving patterns in its perceptual input and in its own processing of that input. When a new answer is found, an answer description can be formed by examining the temporal record in the Trace to see which events contributed to the answer's discovery.

This approach is similar in flavor to work on derivational analogy, in which the trace of a problem-solving session is stored in memory for future reference, together with a series of annotations describing the conditions under which each step in the solution was taken (Carbonell, 1986; Veloso, 1993). In Metacat's case, however, the information in the Trace is used as the basis for constructing an abstract description of the answer found, rather than being permanently stored itself.

One way to appreciate the abstract, chunked nature of the information in the Trace is to consider the number of "steps" that occur during a typical run of Metacat. At a very fine-grained level of description, where each step corresponds to an action performed by a single codelet, a run consists of many hundreds or thousands of steps. At this level of description, no two runs are ever *exactly* the same, even if they involve the same letter-strings (unless, of course, both runs start with the same random number seed). On the other hand, at the level of description of the Trace, a typical run consists of a few *dozen* steps. At this level of granularity, each step corresponds to a single event represented in the Trace—each of which arises from the actions of many codelets.

For example, Figure 1 shows the contents of the Trace after a run on the problem " $abc \Rightarrow abd$; $xyz \Rightarrow ?$ ", in which the program, after trying unsuccessfully a couple of times to take the successor of *z*, answers *xyd*. The events that occur during the run appear left to right in chronological order. Although this run involves a total of 1,558 codelets, the high-level picture shown in the Trace consists of just twelve events, which represent the "major milestones" encountered along the way in the program's search for an answer. Such events include the activation of concepts in the Slipnet, perceiving entire strings as single, chunked wholes, creating new rules for describing string changes, hitting a snag, and discovering a new answer.

For instance, as can be seen in the figure, the Slipnet concept *identity* gets activated early on in this particular run (due to the program perceiving the *a*'s and *b*'s in *abc* and *abd* as corresponding). This is followed by the perception of *abc* and *xyz* as *predecessor* groups going in the same direction (to the left). The next event records the creation of the rule *Change letter-category of rightmost letter to successor* for describing $abc \Rightarrow abd$, which leads inevitably to a snag. In the aftermath of the snag, another rule is created (*Change letter-category of rightmost letter to 'd'*), and *abc* and *xyz* are reperceived as *successor* groups (again going in the same direction—only

Figure 1: The temporal record of a run on the problem " $abc \Rightarrow abd; xyz \Rightarrow ?$ ".

this time to the right). However, the program again attempts to use the first rule, resulting in another snag. Finally, after creating yet another rule and again perceiving *xyz* as a successor group, the program finds the answer *xyd*.

Pattern-clamping and Self-control

The Trace allows Metacat to monitor the subcognitive processing activity in the Workspace at a very abstract and highly-chunked level of description, enabling the program to "see" what it is doing during a run. Equally important, however, is the program's ability to *respond* to what it sees by clamping particular themes and concepts at high activation, resulting in strong top-down pressure on processing. Various types of *patterns* consisting of sets of themes, concepts, or codelet types can be clamped by the program in response to different situations that arise. Clamping a pattern alters the probabilities that certain types of codelets will run, or that certain types of Workspace structures will get built, effectively steering the behavior of the program in particular directions. This may lead the program to revise its interpretation of a problem, by catalyzing the reorganization of structures in the Workspace in accordance with the ideas represented by the pattern.

Metacat's ability to revise its perception of a situation in response to events in the Trace affords the program a very powerful degree of self-control. Patterns—especially patterns of themes—act as a "medium" through which the program is able to wield control over its own behavior. For example, in the problem " $abc \Rightarrow abd; xyz \Rightarrow ?$ ", the program usually perceives *abc* and *xyz* as going in the same direction at first, which leads to a snag (as in the run shown in Figure 1). This interpretation of the problem, based on the idea that letters having identical positions in their respective strings correspond to one another (*a* to *x*, *b* to *y*, *c* to *z*), is characterized by a *String-Position:identity* theme. When an event is recorded in the Trace, the themes most active at the time of the event are also noted along with it. These themes serve as the event's *thematic characterization*. In the case of a snag event, the thematic characterization represents an interpretation of the problem that has just led to failure. If Metacat continues to hit the same snag several times in succession, a series of snag events will accumulate in the Trace, all with very similar thematic characterizations. This similarity may be noticed by

codelets (the probability becoming higher as more snags accumulate), causing them to take action by clamping the "offending" themes (such as *String-Position:identity*) with strong negative activation. This encourages the program to explore alternative interpretations of the problem by steering it away from the ideas causing the snag, which may subsequently lead it to the discovery of other answers, such as *wyz*. In this way, Metacat can recognize its own repetitive behavior and respond accordingly.

Two types of codelets are responsible for examining and responding to events unfolding in the Trace. The first type, called a *Progress-watcher*, is responsible for deciding whether or not to unclamp a clamped pattern. If a *Progress-watcher* codelet runs while a pattern is clamped, it examines the most recent event in the Trace to determine how much time has elapsed since the event occurred. Generally speaking, the purpose of clamping a pattern is to precipitate a series of events that reorganize the perceptual configuration of the Workspace in some way. It is therefore better to wait until the structure-building activity occurring in the wake of a clamp has settled down before concluding that the clamp has "run its course". Accordingly, if the amount of time since the most recent event in the Trace is less than some minimal settling period, then the codelet simply fizzles, leaving the clamped pattern still in effect. On the other hand, if enough time has passed without any new important events having transpired, the codelet unclamps the pattern and then determines the amount of progress that was made since the clamp occurred. Depending on the amount of progress achieved, the codelet may decide to post a follow-up codelet in order to see whether a new answer can be made based on the newly-created structures.

The criteria for judging the success of a clamp can vary. Sometimes, the purpose of clamping a pattern is to promote the creation of *specific* types of Workspace structures. Other times, the purpose is to encourage the creation of structures of *any* type, so long as they are compatible with the clamped pattern. The progress achieved by a clamp can be measured by observing the number of structures that get built in the immediate aftermath of the clamp, and the extent to which they are compatible with the pattern.

If no patterns are clamped when a *Progress-watcher* codelet runs, then instead of checking on the progression of events in the Trace, the codelet

checks on the current rate of structure-building activity in the Workspace. This activity is measured by a single number that serves as a quick estimate of the “freshness” of the current Workspace structure configuration. More precisely, it is an inverse function of the average age of the most recently created structures. Thus the activity level tends to remain high as long as new structures are being built, but eventually drops to zero in the absence of new structures.

If the activity level is zero, indicating that nothing much is happening in the Workspace, then Metacat may have arrived at an impasse in its search for answers to the current problem. This is not quite as bad as hitting a snag, but it still ought to prod the program into trying something different. However, in the case of an impasse, there is usually no clear set of “offending” structures or themes on which to pin the blame, unlike in the case of a snag. Indeed, the impasse may well arise from a *lack* of appropriate structures, rather than from the existence of the “wrong” structures.

Therefore, in the absence of Workspace activity, *Progress-watcher* codelets check to see whether particular types of new structures are needed. For example, a codelet may examine the quality of the rules that have been built so far. If no good rules yet exist, the codelet may try to encourage the creation of better rules by clamping a pattern that strongly increases the probability that rule-seeking codelets will run, while simultaneously inhibiting other types of codelets. Eventually, other *Progress-watcher* codelets will turn off the clamp once enough time has passed without any more events being added to the Trace. Since this type of clamp is only concerned with the creation of new rules, the amount of progress achieved is judged solely on the basis of the quality of the rules that get created in the clamp’s wake.

The second type of codelet that “watches the action” from the high-level vantage point of the Trace is called a *Jootser* (short for “jumping out of the system”). These codelets are responsible for noticing repetitive behavior that the program has fallen into. An example of such behavior arising from a snag was sketched above. However, *Jootser* codelets are sensitive to other kinds of situations as well. For example, it is possible for Metacat to become “fixated” on some idea, such that it ends up clamping the same pattern over and over again, without making any significant progress. In this case, too, *Jootser* codelets may notice the series of recurring events in the Trace and take action.

For instance, if an analogy problem happens to involve a string that changes in some difficult-to-describe way, the program may end up repeatedly clamping patterns in an attempt to spur the creation of better rules for describing the change. Repetitive clamping behavior can even arise from unsuc-

cessful attempts to break out of a cycle of snags. That is, clamping a pattern in response to a recurring snag may prove to be ineffective, leading only to further snags and more pattern-clamping, rather than to a new interpretation of the problem. Faced with several similar clamp events in the Trace, a *Jootser* codelet decides probabilistically whether to “joots” based on the number of clamps and the average amount of progress achieved by each. The more clamp events there are, the more likely jootsing is to occur, especially if the amount of progress is low, unless recent clamps appear to be making more headway than earlier ones. Unlike jootsing from snags, however, jootsing from a series of recurring clamp events does not involve the clamping of any new patterns in response. Instead, Metacat simply “gives up” in a graceful manner and stops.

In a sense, Metacat’s ability to respond to a recurring snag by focusing on alternative ideas can be thought of as “first-order” jootsing. In contrast, the program’s ability to eventually give up when it recognizes that its repeated attempts to circumvent a snag are leading nowhere can be thought of as “higher-order” or “meta-level” jootsing (i.e., jootsing from repeated unsuccessful jootsing). The important point is that the same general mechanisms are responsible for first-order and meta-level jootsing in Metacat—namely, *Jootser* codelets and the explicit representation of processing events in the Trace.

An Example of Jootsing

The following example illustrates the idea of jootsing. In this run, Metacat is given the problem “*eqe* \Rightarrow *qeq*; *abbbc* \Rightarrow ?”. The program builds up an interpretation of the string *abbbc* as a successor group composed of the letter *a*, the group *bbb*, and the letter *c*. The two rules shown below are also created to describe the *eqe* \Rightarrow *qeq* change:

- Swap letter-categories of all objects in string
- Change letter-category of leftmost letter to ‘q’
Change letter-category of middle letter to ‘e’
Change letter-category of rightmost letter to ‘q’

Around time step 1100, the program attempts to apply the first rule to *abbbc*, which results in a snag, since the idea of a three-way swap involving the letters *a*, *b*, and *c* makes no sense (see Figure 2). Of course, if it had chosen to use the second rule instead of the first, then it would have found the answer *qeeeq*, but it prefers the first rule, since this rule is more abstract.

Over the next 3000 time steps, the program tries again and again to swap the letters of *abbbc*, often breaking various structures in the process, but always rebuilding them in the same way as before. Eventually, at time step 4280, a *Jootser*

Figure 2: Attempting to swap the letters of *abbbc*

codelet notices the pattern of recurring snag events in the Trace, all of which involve the themes *String-Position:identity*, *Object-Type:identity*, and *Object-Type:different*. These themes arise from the program's interpretation of the letters *e*, *q*, and *e* in *eqe* as corresponding, respectively, to the letter *a*, the group *bbb*, and the letter *c* in *abbbc*. The *Object-Type:identity* theme is based on the *e-a* and *e-c* correspondences, while the *Object-Type:different* theme results from the correspondence between *q* and *bbb*, since one is a letter and the other a group.

In hopes of finding a way around the recurring snag, the codelet decides to negatively clamp the *Object-Type:identity* theme. In the wake of the clamp, *abbbc* is reinterpreted as a predecessor group going to the left, and a new rule is created to describe *eqe* \Rightarrow *qeq*, but these new structures do not really change the basic situation. Soon afterwards, another *Jootser* codelet tries again, this time clamping both *Object-Type* themes, which essentially "paralyzes" the program for the duration of the clamp, since no structures can be built that are compatible with both of these themes simultaneously. Figure 3 shows the state of the Workspace and Trace at the time of the second clamp.

A few hundred codelets later, the program hits the snag again. This is followed shortly thereafter by another clamp. This clamp, like the one before it, achieves no new progress. After hitting the snag yet again, the program finally decides to give up. More precisely, at time step 5933, a *Jootser* codelet notices the three clamp events in the Trace, all of which involve overlapping thematic characterizations. Moreover, neither of the two most recent clamps have resulted in any discernible progress, which further increases the probability of jootsing. Consequently, the program prints the message "this is getting boring, I can't think of anything else to try" and then

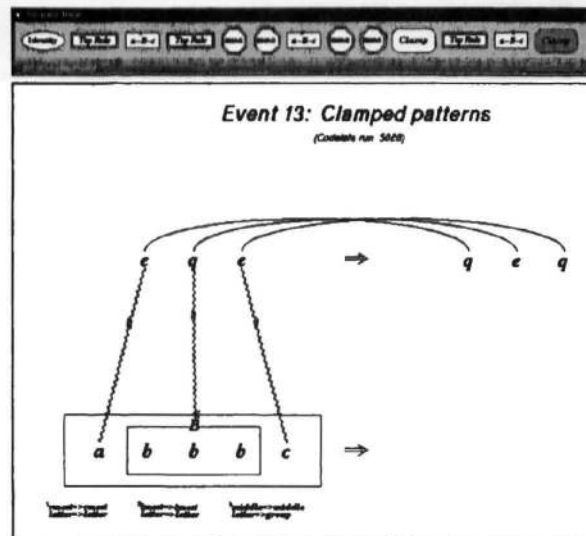

Figure 3: Clamping patterns in response to snags

ends the run.

As this example shows, Metacat is able to realize when it is "stumped", instead of just cycling endlessly. The program's ability to monitor its own processing at an abstract level of description affords it a great deal of flexibility and self-control, and, it is to be hoped, represents a step toward the goal of understanding the cognitive mechanisms underlying human self-awareness.

Where do syllables come from?

Abstract

Young children are able to segment words into syllables, even though there are no perceptual or acoustic cues that indicate syllable boundaries in the primary linguistic data. We show that information about word boundaries can be used to predict syllable boundaries by replicating the results of experiments done by Gillis and De Schutter (1996) with children who syllabified Dutch disyllabic monomorphemes with a single intervocalic consonant. Word boundary probabilities were statistically computed in child language corpora and used to predict syllable boundaries with a simple statistical model. The children's syllabification behavior could be simulated using word-boundary probabilities estimated from child language corpora. Similar results were obtained for three different corpora. In our simulations, we also investigate the question whether children acquire their knowledge of word boundaries from words from the input, from the intake, or from their own output.

Introduction

The syllable is an important construct in phonological descriptions of languages (Van der Hulst & Ritter, 1999) as well as in models of language acquisition (Jusczyk, 1997) and language processing (Levelt, 1989). In most contemporary phonological theories the syllable plays an important role at the segmental level (e.g., in consonant harmony) as well as at the supra-segmental level (e.g., in stress assignment). Across languages syllables adhere to a number of universal principles (Venneman, 1988) and Clements (1990) proposes a universally valid algorithm for syllabifying words. One of its operating principles is 'sonority sequencing': a syllable has rising sonority from the left edge to the vocalic nucleus and falling sonority from the vowel to the right edge. Irrespective of the theoretical framework in which the universals of syllabification are cast, it is accepted that the language universals, such as those incorporated in Clements' algorithm, can be overruled by language-specific constraints. For instance, at the end of a syllable long vowels are universally accepted, but languages differ as to whether there can be a short vowel at the end of a syllable (Kager, 1989).

In sharp contrast to the relatively clear phonological picture stands the phonetic reality: what are the acoustic correlates of the syllable in the speech stream? For instance, acoustic correlates of the 'sonority sequencing principle' are very difficult to determine, which led phoneticians to define the syllable from a phonetic point of view as that entity of which the word *syllable* has three. The syllabic nucleus (the vowel) is fairly easy to detect, but the syllable boundaries are not straightforward. For instance, the /I/ in *bitter* is the nucleus of the first syllable, but where is the boundary of that syllable: immediately after the vowel /bIt@r/ or after the first consonant /bIt.@r/ or in the middle of the first consonant /bIt.t@r/, a case of ambisyllabicity? This brings us to the core issue addressed in the present paper: if from a structural perspective syllables are easy to describe, but if it is very difficult to depict the acoustic correlates of the syllable and its boundaries, it is an outstanding question how children arrive at detecting syllables and their boundaries.

Nevertheless, in early speech perception (Jusczyk, 1997) as well as in speech production (Wijnen, 1988) children appear to use syllables as organizing entities. The question is: how does a child acquire the knowledge of the structure of syllables?

In the acquisition literature there are basically two approaches: in a nativist approach, the universals of syllable structure are thought to be innately given: they are described as inborn parameters (Fikkert, 1998), or as inborn constraints (Kager, 1999; Levelt, Schiller, & Levelt, 2000). Acquiring the structure of syllables requires a child to figure out the language-specific parameter setting or the language-specific constraint ranking. Thus, the broad outlines are genetically given, so that only on the basis of the ambient language the child has to determine where precisely her mother tongue fits into these outlines. Appealing as this may sound, it is unclear on what basis parameters are set or constraints are ranked. The cues for parameter setting or constraint ranking can only be found in the input. However, the acoustic correlates of the syllable are not clear in the input (see second paragraph).

The alternative approach is that children do not start from a preset body of knowledge, but instead

use the information available in the input to arrive at linguistically relevant knowledge. For instance, Brent and Cartwright (1996) found that word boundaries can be learned on the basis of utterance boundaries. In a similar vein we want to investigate if syllable boundaries can be learned on the basis of word boundaries. Word boundaries are clear and usable cues, because words often occur in isolation in child-directed speech (van de Weijer, 1998; Brent & Siskind, 2001). Thus, the hypothesis tested in this paper is that syllable boundaries are learned on the basis of word boundaries.

In this paper we will test this hypothesis in a simulation experiment. The results of the simulations will be evaluated in the light of children's actual syllabification behavior. Gillis and De Schutter (1996) tested 5- and 6-year-old native Dutch-speaking children in a syllabification task: they syllabified disyllabic Dutch monomorphemes with a single intervocalic consonant, such as /Ap@l/ 'apple'. The children segmented the test words orally and of the possible syllabifications (V.CV, e.g. /A.p@l/, VC.V, e.g. /Ap.@l/, and VC1.C1V, e.g. /Ap.p@l/) the preferred syllabification pattern was V.CV (81.6%), i.e. before the intervocalic consonant. The next most frequent syllabification was the ambisyllabic pattern VC1.C1V (17.8%), and the children almost never (0.4%) put a syllable boundary after the intervocalic consonant (VC.V). Furthermore, children's syllabification of the intervocalic appeared to depend on the length of the preceding vowel, the stress pattern of the word, and the quality of the intervocalic consonant. These results will be taken as the background against which the results of the simulations will be evaluated.

Naive Bayesian learning of syllabification

Whether it is possible to learn syllable boundaries from information about word boundaries will be investigated with a naive Bayesian learning technique. A simple statistical model uses estimated word boundary probabilities of segments to predict syllable boundaries. This model takes into account the probability that a phoneme occurs at the end of a word and that the following phoneme occurs at the start of a word, and combines both features in a multiplicative way. Such a model does not take into account interactions between the features, hence Naive Bayesian learning, a well-known supervised learning approach (Mitchell, 1997). However, we don't use a normal supervised learning set-up in which training and testing is on the same data. In our case, training is on word boundary information and extrapolation is to syllable boundary decisions.

In the training data, the word-initial boundary probability and the word-final boundary probability of every phoneme are computed. This is done

by counting the number of times the phoneme is at the end of a word (e), the number of times the phoneme is at the beginning of a word (b), and the total number of times that phoneme occurs (t). For every phoneme the word-initial boundary probability and the word-final boundary probability are then computed in the following way:

$$p(\text{beginning(phoneme)}) = b/t$$

$$p(\text{end(phoneme)}) = e/t$$

The model's task is to predict the syllable boundary in disyllabic monomorphemic Dutch words with one intervocalic consonant. To compute the probability of a syllable boundary between two phonemes of a test word, the word-final boundary probability of the first phoneme, and the word-initial boundary probability of the second phoneme are multiplied. This is done for the two possible syllabifications of the test word, considering that every syllable must contain a vowel.

E.g. *appel*, /Ap@l/, 'apple'

$$p(\text{end(A)}) * p(\text{beginning(p)}) = p(\text{V.CV})$$

$$p(\text{end(p)}) * p(\text{beginning(@)}) = p(\text{VC.V})$$

For all the test words the probabilities of V.CV and of VC.V are computed. I.e. the probability that the syllable boundary falls either before or after the intervocalic consonant. Ambisyllabicity occurs if the difference between those two numbers does not exceed a maximum limit. If it does, the pattern with the highest probability is chosen. This method forces the model to syllabify and to choose one of three syllabification patterns. No syllabification occurs, though, if the probability for both V.CV and VC.V is zero. This way, a fourth category of "no syllabification" is created, to make sure these cases are not counted as ambisyllabicity.

For n = threshold:

$$\begin{aligned} \text{if } & p(\text{V.CV}) = 0 \text{ and } p(\text{VC.V}) = 0 \\ & \rightarrow \text{no syllabification} \\ \text{else if } & |p(\text{V.CV}) - p(\text{VC.V})| < n \\ & \rightarrow \text{VC1.C1V (ambisyllabic)} \\ \text{else } & \max(p(\text{V.CV}), p(\text{VC.V})) \end{aligned}$$

As the probabilistic model is trained on a two-way classification problem (either there is a word boundary or not), and the target classification problem is four-way (ambisyllabic, before or after the intervocalic consonant, no syllabification), we fixed the model on the proportion of ambisyllabicity found in the empirical data by setting the n threshold. This threshold value is determined by the amount of ambisyllabicity. The percentage of ambisyllabic syllabification is put as close as possible to 17.8%, which is the percentage of ambisyllabicity found in the experiments by Gillis and De Schutter (1996).

The fixing of a threshold parameter on the test data to be explained is an unfortunate consequence of the fact that the training data (word segmentation information) does not contain a similar concept to

ambisyllabicity at the syllable level. Nevertheless, the threshold value seems to be rather robust over different training data sets, and could be learned with simple hill-climbing type of algorithms (there is a smooth gradient).

Research questions

Considering the different factors that might play a role in syllabification, a number of research questions were formulated.

1. What is the nature of the child's primary linguistic data? To acquire knowledge of language, children may analyze all the language that they hear or that is addressed to them (i.e., child-directed speech). Alternatively, it may well be that it is not the *input*, but the *intake* (i.e., what the child picks

up from the input) (Wijnen, 2000) that is crucial for analysis. Alternatively, proponents of the output-as-input hypothesis (Elbers, 2000) argue that the input for children's linguistic analysis is primarily their own production, their own *output*.

2. What type of words is children's language analysis based on? Judging from the absence of function words in children's early productive vocabulary, it may well be that only content words are vital. And since syllables play a role in children's earliest word productions (Fikkert, 1998), it is important to investigate if syllabification can be acquired solely on the basis of content words as opposed to function words.

Judging from the predominance of monosyllabic words in children's early production (or even the fact that all children initially exclusively produce monosyllables (Fikkert, 1998)) also the opposition between monosyllables and polysyllables will be investigated.

3. What is the influence of frequency on the acquisition of syllabification? Frequent words in the input are more salient for children (Jusczyk, 1997). However, Schreuder and Baayen (1997) found that the word frequency effect is composite in nature in the sense that it has both a token and a type component.
4. What is the optimal representation? Are words best represented as phonemes, or as phoneme categories? And is stress part of the representation?

Phoneme categories express distinctive articulatory and acoustic features of phonemes, which is the reason why they differ in their scale of sonority. Sonority is regarded as important in syllabification, e.g. the universal Sonority Sequencing Principle describes syllables in terms of rising and falling sonority (Selkirk, 1984; Clements, 1990).

Stress as well has been suggested as a determining factor in syllabification. There is a significant interaction between stress and length of the first vowel (Gillis & De Schutter, 1996), and there is less syllabification after the vowel if the first syllable is stressed than if it is unstressed (Wijnen, 1988).

In the following sections, we will report on experiments in which these dimensions are systematically encoded in the training data. The degree to which the resulting syllabification behavior of our statistical model matches the empirical data may have heuristic value to answer the question which dimensions of language data and representation are relevant in explaining this aspect of language acquisition.

Experiments

The input for the learner consisted of data taken from three Dutch child language corpora, all available through CHILDES (MacWhinney, 2000). The research questions were translated into different selections of input material and different types of input representations that were systematically varied in order to figure out their influence on the learnability of the task. Experiments were performed

1. using as training material the input to the child, the child's intake, and the child's output (the concept of intake was operationalized by using the actual adult model form of a child production, which makes intake a subset of the input);
2. using as training material different types of words: all words vs. content words, monosyllabic vs. polysyllabic words;
3. with information about word frequencies: word types vs. word tokens, as calculated from the corpora;
4. in which the representation of the input was varied: raw segmental material (phonemes) vs. segment categories (stops, fricatives, nasals, liquids, glides, and vowels) both with and without primary stress marking.

Combining all these factors in three child language corpora leads to a total of 136 experiments. In each case, the test material consisted of the words that were used in the experiment with children (Gillis & De Schutter, 1996) (see introduction). The artificial learner is set to the same task as the children: predicting the syllable boundary in Dutch disyllabic monomorphemes with a single intervocalic consonant. Hence, the learner has to decide whether for a given word (e.g. *appel*, /Ap@l/, 'apple') the string VCV should be syllabified as V.CV (/A.p@l/), VC1.C1V (/Ap.p@l/) or VC.V (/Ap.@l/).

For the different datasets, word boundary probabilities are computed with a naive Bayesian learning technique as described above. The amount of ambisyllabicity will be more or less the same for all the experiments (as close as possible to 17.8%), because the threshold (η), which is needed to get this percentage of ambisyllabicity, is dataset-specific. It is the percentages of syllabification after the vowel and after the intervocalic consonant, and the amount of "no syllabification", which are of interest. The results will be evaluated by comparing the proportions of the chosen syllabification patterns using word boundary probabilities to those of the children in the experiment by Gillis and De Schutter (1996). This means very little syllabification after the intervocalic consonant (0.4%) and most syllabification after the vowel (81.6%) are best.

Results

In this paragraph we will systematically take up the research questions formulated above and discuss what answer is suggested by the results of the simulation experiments. We will then propose the characteristics of the 'optimal' simulation, i.e., the one that most closely matches the results of the experiment with children.

Overall effects

1. What is the nature of the primary linguistic data?

It is not clear from the simulation experiments' results whether language input, intake or production is the source of linguistic knowledge.

Overall, there is less syllabification after the intervocalic consonant and less after the vowel in experiments using input or intake than in experiments using language output (Table 1).

Table 1: Average results over all simulation experiments using input vs. intake vs. output.

	V.CV	VC.V
input	51.9%	18.3%
intake	50.8%	16.4%
output	57.9%	23%

2. What type of words is the language analysis based on?

The results suggest that content words — both mono- and polysyllabic — are the words used in a syllabification task.

On average, there is less syllabification after the intervocalic consonant and more after the vowel in experiments using content words than using all words. The results of experiments using both mono- and polysyllabic words are better than

those using only monosyllabic words. There is less syllabification after the consonant and more after the vowel with monosyllabic content words (types) than with all monosyllables (types or tokens), but there is more syllabification after the consonant and less after the vowel with monosyllabic content words (tokens) than with all monosyllables (Table 2).

Table 2: Average results over all simulation experiments using all words vs. content words vs. monosyllables vs. monosyllabic content words.

	V.CV	VC.V
content words	60%	6%
monosyll. content words types	51.1%	7.7%
all words	59.8%	19.8%
monosyllables	44.6%	30.1%
monosyll. content words tokens	17.3%	39.2%

3. What is the influence of frequency on the acquisition of syllabification?

The simulation experiments suggest that linguistic analysis is based on word types rather than on word tokens.

If information of word tokens is taken from child language corpora as training material, syllabification occurs more often after the intervocalic consonant and less after the vowel than when word types are used (Table 3).

Table 3: Average results over all simulation experiments using word types vs. word tokens.

	V.CV	VC.V
types	55.9%	14.2%
tokens	48.2%	21.5%

4. What is the optimal representation?

A representation in phoneme categories appears to be more appropriate than a representation in phonemes.

Using phoneme categories instead of phonemes generally gives better results, because with phonemes "no syllabification" is often assigned. The amount of test words for which the probabilities for V.CV and for VC.V are both zero can reach up to 81.1%. With phoneme categories, on the contrary, there are no test words that do not get syllabified (Table 4).

The effect of stress marking in polysyllabic words is not univocal (Table 5). Using phoneme categories, there is less syllabification after the vowel

and less after the consonant with stress marking; using phonemes, stress marking has the opposite effect. Thus, stress has a differential effect depending on the representation of the segments.

Table 4: Average results over all simulation experiments using a representation in phonemes vs. phoneme categories.

	V.CV	VC.V	no syll.
phoneme categories	68%	12.9%	0%
phonemes	36.1%	22.8%	22.5%

Table 5: Average results over the simulation experiments with polysyllabic words using a representation with vs. without stress marking.

	V.CV	VC.V
phoneme categories without stress marking	79.2%	4.3%
phoneme categories with stress marking	76.1%	4.1%
phonemes without stress marking	37.7%	21.6%
phonemes with stress marking	39.5%	22.2%

These tendencies concerning the composition and the representation of the input material are found over the total of all 136 experiments. Now we will discuss the individual experiments that most closely match the behavior of children.

Best results

Similar syllabification patterns ($\chi^2=1.16$, $p>0.05$) to children's intuitive syllabifications in the experiments by Gillis and De Schutter (1996) are obtained when word boundary probabilities are computed in content words from the intake (types or tokens) or from the input (types) of a child language corpus, represented in terms of segment categories without stress assigned. These results are robust over the three language corpora, in the sense that we find the same results as displayed in figure 1 for the three corpora.

Not only the proportions of the syllabification patterns of the Naive Bayesian learner are similar to children's. Also the factors that influenced the children's syllabification patterns were replicated in the simulations. We will restrict the discussion to the factor of consonant quality.

Gillis and De Schutter (1996) found that children give significantly less ambisyllabic responses if the intervocalic consonant is a stop (3.4%) than if it is a

Figure 1: Comparison of syllabification patterns in five- and six-year-olds with results of simulation experiments using content words from input (types) or intake (types or tokens) in phoneme categories.

continuant (19.5%). Looking at the predicted syllable boundaries in the experiments, there are significantly less ambisyllabic responses as well if the intervocalic consonant is a stop (0%) than if it is a continuant (19.4%) ($\chi^2=9.05$, $p<0.01$). This concerns the same training material, i.e. content words in phoneme categories from intake or input.

The observation that a simple statistical model trained on word boundary information (of content words in the input and using a representation in terms of phoneme categories) produces a tight fit with syllabification behavior in children, and the additional evidence that the model matches the children's behavior even at a detailed level of consonant quality is a strong existence proof of the possibility of data-oriented acquisition of the concept of syllables and of syllabification behavior.

Conclusion

Five- to six-year-old children that can't read nor write yet are able to syllabify disyllabic monomorphemic words according to universal rules of syllabification (Gillis & De Schutter, 1996). In this paper, we hypothesized that this intuitive knowledge of syllable boundaries is learned by attending to word boundaries.

To test this hypothesis, statistical word boundary probabilities of phoneme categories were used to predict syllable boundaries in disyllabic monomorphemes with one intervocalic consonant. To compute the probability of a syllable boundary between two phoneme categories, the word-final boundary probability of the first phoneme category and the word-initial boundary probability of the following phoneme category were multiplied. If the difference between the probabilities of the two syllabification possibilities (V.CV and VC.V) does not exceed a maximum limit, ambisyllabicity was assigned (VC1.C1V). Otherwise, the syllable boundary with the highest probability was chosen.

Using this naive Bayesian learning technique, similar syllabification patterns to children's intuitive syllabifications in the experiment by Gillis and De Schutter (1996) were obtained. Best results were achieved when the words used as material to compute word boundary probabilities were content words from the intake (types or tokens) or from the input (types) of a child language corpus, represented in phoneme categories. The same results were found with words from three different child language corpora. Moreover, the quality of the intervocalic consonant has a similar effect on children's intuitive syllabification and on the simulations using word boundary probabilities for syllabification. In both cases there is significantly less ambisyllabicity if the intervocalic consonant is a stop than if it is a continuant.

We have given an existence proof of the hypothesis that syllable boundaries can be learned from word boundaries. The fact that extrapolation from word boundaries to syllable boundaries can be modeled with such a simple statistical mechanism lends support to our initial hypothesis. Furthermore, varying the representations and input data used by this simple statistical learner, we were able to derive a number of interesting more detailed hypotheses about the type of representations and input children may use. More in particular, our results suggest syllable boundaries are most reliably learned from **content words'** boundaries. The semantic saliency of content words seems to be reflected in language production. Moreover, the best results are obtained using **phoneme categories**, rather than the phonemes themselves. This points at the role of sonority in the production of syllables. Phonological saliency is also shown to be an influencing factor, since disyllabic words with intervocalic stops are syllabified significantly differently from disyllables with intervocalic continuants. Finally, we found that the material that worked best to compute boundary probabilities are words from the **intake** or from the **input** of child language corpora. This suggests that children's productions — in this case intuitive syllabifications — could be based on their language input rather than on analysis of their own output. All these findings and predictions from the model have to be further investigated.

Abstract

Interpretation of data is a critical part of scientific experimentation because it involves applying one's background theoretical knowledge to the characteristics of the data. Though many researchers have examined the impact of background knowledge, few have considered the impact of the characteristics of the data in making decisions. In this study, we presented 3rd graders, 6th graders, and college undergraduates with a series of datasets that varied in sample size, consistency in data pairs and variability relative to the mean. We found that at all ages, participants showed sensitivity to sample size and whether or not there were overlapping data points in comparative datasets, but that there were age differences in the justifications used and in conclusions drawn from the data.

Interpretation of data is a critical part of scientific experimentation. Expectations about features of the data have been suggested as an important component in assessing data (Kahneman & Tversky, 1973). These expectations are based both on theoretical knowledge about the domain under consideration and on features of the data itself. While a large body of research in scientific thinking examines the influence of domain theory on the evaluation of data (e.g., Klahr, 2000; Koslowski, 1996; Kuhn, Garcia-Mila, Zohar, & Andersen, 1995), little is known about how the characteristics of data influence how children and adults interpret it.

An important component of science is distinguishing real effects from error, or effects caused by factors other than the ones being explored. In the science laboratory, statistics is a vital tool to help make these decisions. When there are differences that are highly unlikely to occur by chance, scientists can feel more confident about drawing conclusions from data.

In daily life, we regularly make decisions about evidence without the aid of formal statistics. In such cases, we resort to relying on theory and expectations. However, there are many situations in which we do not have strong background information, and thus only have evidence based in the data. Elementary school students seem likely to have an especially large handicap in evaluating data – they have a smaller knowledge base

about the world and also have less formal knowledge about statistics and its applications.

Students in elementary school are beginning to learn about experimentation and data interpretation, and third through sixth grade is a time of important increases in understanding of basic science fundamentals, such as the control of variables strategy (e.g., Chen & Klahr, 1999). In addition, elementary school teachers routinely assign children to perform repeated trials of events, explaining that this is how science is done (Klahr, Chen & Toth, 2001). In evaluating data in and out of the classroom when children do not know formal statistical techniques, we expect them to rely on their informal knowledge of the area.

But what constitutes “informal” notions of statistical reasoning? We suggest two components: expectations about data distribution and expectations about the influence of sample size. Some research that has examined expectations for the distribution of data has looked at probability estimates. For example, when given data about a series of coin flips, participants expected that a coin would land on “heads” every other flip (Gilovich, 1991). This suggests that the participants had an implicit expectation of the distribution of data in a series of coin flips and that the judgment of “randomness” was (at least in part) based on a mapping between expectations and data patterns. More recently, some have argued that children as young as five or six have a functional understanding of probability (Schlottman, 2001).

Although there is related research in several areas, few studies focus explicitly on the characteristics of the data and the effects this focus has on conclusions. There is some evidence that children at different ages do recognize different properties of datasets, and that this recognition in turn affects the conclusions they draw. For example, Jacobs and Narloch (2001) found that children as young as seven could use sample size and variability information in inferring the likely frequency of a future event. The differences in variability were based on prior knowledge of base rates (i.e., how many elephants have two eyes, compared to how many birds are a specific color). The sample sizes used in this study varied dramatically, with either 1, 3, or 30 instances of an event before the

participant was asked to infer likelihood of other instances of the event, so it is unclear what sample size leads children to feel confident in their predictions.

However, there is also some evidence that children at ages 11 are still struggling to understand the value of repeated measurements within the context of a school science laboratory (Lubben & Millar, 1996). Some children at this age believe repeated measurements are important, but 18% thought that repeated measures are useful because they accommodate scatter in the data.

There is also some evidence that children can distinguish different kinds of variability. Masnick and Klahr (2001) examined second and fourth graders performing experiments in which two balls were simultaneously rolled down ramps and the distance each travels was measured. The children expected that on a new trial using the same experimental set-up, the relative positions of the two balls would remain the same, but that the precise location of each ball might be different. That is, they were able to make a distinction between small differences in individual data points and larger differences in sample means.

Students' expectations about the essential features of data and the features of a specific dataset may allow them to recognize data as consistent or inconsistent with their expectations about its distributions. These expectations may in turn guide decisions about the usefulness of the data and the extent to which the data are relevant to explanatory theories. Thus, the characteristics of the data partly determine the extent to which they are used to guide the formation or modification of explanatory theories.

One related body of research has examined how children use data (in this case covariation between events) to detect causal relationships between elements (Shaklee & Mims, 1981; Kuhn, 1989). These studies looked at how children evaluate evidence when events occur together all the time, some of the time, or none of the time.

In a series of studies by Shaklee and her colleagues, students in grades 2-8 and adults were presented with data about two events (e.g., plant growth-healthy/unhealthy and use of bug spray- yes/no) in a 2x2 contingency table. From these data, students were asked to determine the nature of the causal relationship between the events (i.e., presence and direction of relationship). A majority of participants at all ages did not use conditional probability rules to determine covariation, yet many children used a strategy for summing the diagonals in the contingency table (Shaklee & Paszek, 1985). However both children and adults could use a conditional probability rule if instructed (Shaklee, Holt, Elek, & Hall, 1988).

Kuhn and her colleagues (Kuhn, Amsel, & O'Loughlin, 1988; Kuhn et al., 1995) extended this line of research and examined the effect of detecting covariation on the participant's prior beliefs about an event. For example

Kuhn et al. (1988) interviewed sixth and ninth grade children about the relationship between consuming different types of foods and catching colds. Information about each child's prior beliefs was used to provide each child with two sets of data: one that confirmed their prior beliefs and one that disconfirmed their prior beliefs. The researchers argued that children did not clearly distinguish theory and evidence because children often distorted the evidence to match their prior beliefs.

Although these studies suggest that data itself is important in detecting causal relationships and in evaluating hypotheses, there is little evidence about the point at which children (and adults) detect covariation in a particular dataset. In fact, in her review of scientific reasoning literature Zimmerman (2000) states that "it is not clear *how large* the difference must be in order to conclude that the two events are related" (p. 115).

If students do rely on evidence to extend or modify a theory, how do they go about such a task? Students' notions of data variability may help them determine how to weigh the potential importance of different types of information. For example, data with little variability may be considered more useful in drawing a conclusion than data with greater variability *a priori*. The relevance of the data to theory may be separately evaluated.

One approach to understanding how children use evidence to extend and modify theories is to look at category induction. In a series of studies, Gutheil and Gelman (1997) presented 8- and 9-year-old children and college adults with series of category exemplars. Participants were asked whether a given property would be expected to occur in a new exemplar. The diversity and sample size of the initial sets were varied. Results suggested that children used diversity and sample size information only in combination, but were unable to use just one successfully to infer category membership. Adults, in contrast, used each property independently, as well as jointly, in inferring category membership. In these studies, however, determining that a set was homogenous or diverse relied on domain knowledge acquired outside of the experiment.

Clearly, patterns of data play a key role in scientific inference, but what characteristics of the data guide inferences about their utility? We suggest that, in drawing conclusions about comparative data, three characteristics that indicate the amount of variation in the data are key: consistency within the patterns of data (i.e., the relative sizes of the data points), the magnitude of differences (i.e., the range of each set of data) and the presence of outliers. Data that show high consistency in the direction of effects, small differences in magnitude and few outliers suggests little variability. Data that shows low consistency in the direction of effects, large differences in magnitude, and many outliers suggests more variability. This information about variability can be assessed increasingly well with a larger number of data

points, increasing the degree to which the data itself can inform an interpretation.

As a preliminary exploration of this area, we presented children and college students with sets of comparative data, and asked them to draw conclusions about differences between the sets. The data were varied systematically in number of data points presented and consistency within the pattern of data.

Method

Participants Thirty nine third graders (mean age = 9.1), seventeen sixth graders (mean age = 11.8), and fifty college undergraduates (mean age = 20.2) participated.

Procedure All participants were interviewed individually. Participants were randomly assigned to one of two conditions. The conditions differed in the cover story for the data presented. In the first condition, each participant was read the following information:

Some engineers are testing new sports equipment. Right now, they are looking at the quality of different sports balls, like tennis balls, golf balls and baseballs. For example, when they want to find out about golf balls, they use a special robot launcher to test two balls from the same factory. They use a robot launcher because they can program the robot to launch the ball with the same amount of force each time. Sometimes they test the balls more than once. After they run the tests, they look at the results to see what they can learn.

In the second condition, we used an isomorphic background story in which two athletes were trying out for one slot on a team in different sports. The coaches asked the participants to perform certain tasks (e.g., hit a golf ball as far as possible) to assess which athlete would be better for the team. This condition was designed to see if adding information about a highly likely potential source of variability (human error) would change participants' responses in any way.

After reading the cover story, the participants were shown a series of datasets, one at a time. For each example, there was data for either two different balls of the same type, which were not given any distinguishing characteristics (e.g., "Baseball A" and "Baseball B"), or for two athletes about which there was no information other than their names (e.g., "Alan" and "Bill"). In the athlete condition, different names were used for each story, to prevent any carry-over knowledge effect. For each dataset, there were 1, 2, 4, or 6 pairs of data. Each page contained two columns of data: one listing the distance the first ball traveled and one listing the distance the second ball traveled.

The datasets varied in (a) sample size, (b) whether the datasets overlapped or not, and (c) in whether the

variability in the data was high or low relative to the means. Each participant received a total of 14 comparisons, with 8 trials including no overlap (sample size 1, 2, 4, and 6), and 6 trials including one or two overlapping data points (sample size 4 with one overlapping data point, and sample size 6 with one and two overlapping data points). Half of the trials had high variability, in which the standard deviation was 15-20% of the mean, and half had low variability, in which the standard deviation was less than 2% of the mean. Each of the fourteen trials tested a different type of sports ball. (See Table 1 for specific examples of the different data characteristics.)

Table 1: Examples of datasets

Example 1: Six data pairs, no overlapping data points, low variability within columns relative to the mean, robot condition

Golf Ball A	Golf Ball B
466 feet	447 feet
449 feet	429 feet
452 feet	430 feet
465 feet	446 feet
456 feet	437 feet
448 feet	433 feet

Example 2: Four data pairs, one overlapping pair (3 out of four times Carla throws farther), high variability within columns relative to the mean, athlete condition

Carla	Diana
51 feet	38 feet
63 feet	50 feet
43 feet	56 feet
57 feet	44 feet

For each dataset, participants were first asked what the engineer or coach could find out as a result of this information and to explain any reasons for their answer. Then they were asked how sure they were about these conclusions. To answer the questions about sureness, participants were offered a four-level scale from which to select their answer, choosing among "not so sure," "kind of sure," "pretty sure," and "totally sure."

Participants were next asked if the robot or athlete launched Ball A again, exactly how far they thought the ball would go, and how sure they were that Ball A would travel X feet. They were asked the same questions about Ball B, and then they were asked how sure they were that the ball they had just named as going the farther distance would actually go farther. For example, if they said that they expected Ball A to travel 50 feet and Ball B to travel 60 feet, they were asked how sure they were that Ball B would travel farther. Again, in addition to rating their

sureness, they were asked to offer any reasons for their choices.

This series of questions was repeated for each of the 14 sets of data.

Results

Measures Participants rated how sure they were about their conclusions four times for each dataset: They gave a rating of their confidence in the initial conclusions drawn from the data, in the predictions they made of exactly how far each ball would go, and about which ball would go farther on the next trial. The ratings were assessed on a four-point scale, converted to a four-point variable, with 1 equivalent to not sure and 4 equivalent to totally sure.

In addition, participants offered reasons for their initial conclusions and final predictions of relative position. These reasons were coded for mention of any of the following factors: the precise proportion of times one ball went farther, a trend in the data, sample size, the magnitude of the difference between the two datasets, whether the datasets overlapped, a property of the ball that affected the results, a property of the robot or athlete that affected the results.

Participants also made specific numerical predictions of how far the two balls would go if launched one more time.

Levels of confidence Mixed model ANOVAs were used to examine the effects of condition, data size, overlap, and variability on ratings of sureness on the four-point scale. For each assessment, data size, overlap, and variability were within-subjects variables, and subject was treated as a random variable.

Across all age groups, there was no effect of condition (robot or athlete) on ratings of sureness. Therefore, on later analyses of these questions, we collapsed the data across conditions.

For conclusions about how sure the engineer or coach could be, based on the original data, that one athlete/ball threw/went farther, there were several notable effects. College students were highly sensitive to sample size, the sixth graders showed a small but not significant trend upwards, and the third graders showed a small but significant inverse trend. The data are summarized in Figure 1. Overall, there was a highly significant effect of grade ($F(2, 1448) = 56.38, p < 0.0001$), with third graders on average much more sure than sixth graders, who in turn were more sure than college students, across all sample sizes smaller than 6.

In addition to sample size, participants demonstrated a sensitivity to the presence of overlapping data points, such that they were less sure of conclusions when the data contained overlapping points. This effect was significant for all grades.

Similar patterns emerged on the assessments of participants' sureness about their predictions, both about

the specific distance the balls would travel, and about which ball they expected to go farther on a repeated trial. The strongest relationships were for the college students, who appeared to always link their sureness rating to the number of data points, the proportion of overlapping data points, and occasionally to the level of variation in the data.

Although similar features in the data affected the level of sureness, there were striking differences in the sureness responses to the different questions. Participants were much less sure about specific predictions than about overall conclusions or about predictions of relative placement on a future trial. Overall, general linear models for each dataset, considering the measure of sureness as a repeated factor indicate a strong relationship between both grade and the specific question asked (i.e., the assessment of sureness for general conclusions, specific predictions and relative predictions). Across all grades, there was a relationship between the level of sureness and what question was asked, but it was weakest in the third graders and strongest in the sixth graders.

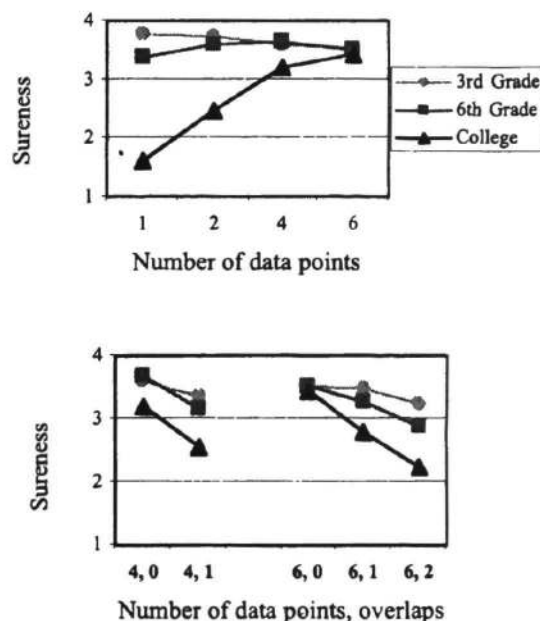

Figure 1: Average ratings of sureness by grade, sample size and number of overlapping data points

Reasons offered Participants offered justifications for confidence in their conclusions and for the predictions they made about which ball would go farther on a subsequent trial. We examined whether participants mentioned each reason at any point in response to a question about each of the fourteen datasets. We then ran Chi-square tests to look for grade differences in the frequency of participants mentioning each factor.

Table 2 presents a summary of these results. An overwhelming majority of the responses were in reference to the data and not to theoretical issues such as properties of the ball or robot/athlete. Young children were most likely to mention either the proportion of the data (e.g., "Five out of six times A went farther") or a trend in the data (e.g., "B generally went farther"). In general, college students used a much wider range of responses than younger children, with nearly all of them mentioning sample size at least once. Interestingly, despite the significant increasing trend, only a small percentage of the participants mentioned within-column variability, one of the factors we manipulated (variability in Table 2).

Table 2: Percentage of participants at each age who mentioned each justification for their sureness ratings

	3 rd Gr.	6 th Gr.	College
Data responses			
Precise proportion	92	86	86
Trend in data*	90	89	100
Sample size**	10	25	96
Overlap	56	64	72
Variability**	0	11	28
No Overlap**	5	7	58
Magnitude of diffs**	36	75	90
Outlier*	0	0	10
Theory responses			
Ball property	8	14	14
Robot/athlete property	18	18	22

Grade differences: * $p < 0.05$; ** $p < 0.01$

Justifications of predictions of which ball would go farther in a new trial followed a very similar pattern as that described above, for all three age groups.

One area in which a condition difference might be expected is in use of justifications that refer to qualities of the ball, the robot, or the athlete. Mentioning the property of the robot or athlete did vary considerably by condition, with nearly all mentions in the athlete condition (i.e., participants sometimes said that a property of athlete was a reason for the outcome, but almost never attributed it to a property of the robot). This trend was even stronger when justifying predictions of future outcomes.

Predictions Participants predicted how far each ball would go if the experiment were repeated. The data from two third graders and one sixth grader were not included in this analysis because they included numbers that differed from the mean by more than twice the range of the data. These outliers skewed the data considerably, and suggested that these participants did not understand the prediction task.

Overall, however, the participants were very good at predicting how far the balls would go, and their

predictions averaged close to the mean. Third graders averaged predictions that were 108.4% of the actual data means ($SD = 10.0$); sixth graders averaged predictions that were 102.7% of the means ($SD = 3.7$); and college students averaged 100.1% of the means ($SD = 1.4$).

Discussion

Our overall conclusion is that in the absence of clear domain knowledge upon which to base theoretical explanations, children and college students paid attention to several features of data. At the same time, there were clear age differences in many responses, indicating changes over time that likely come from a combination of education, experience, and development.

In all age groups, participants were less confident about conclusions from datasets in which there were overlapping data points, indicating a sensitivity to variation in the patterns of the data. College students were significantly more confident when there were more data points, though third graders were actually slightly more confident with smaller sample sizes. It is possible that the third graders were overwhelmed by the variability and became more confused about drawing conclusions when there were more data points to consider.

Participants also showed an appreciation for some types of variability by differentiating their sureness ratings for different types of predictions. At all ages, they were more sure of conclusions about relative distances on a future trial than about specific distances, with the effect most pronounced in college students. This response pattern indicates an expectation that variation is more likely in precise measurements than in overall patterns of results. Participants seemed less attuned to within-column variability in the data, rarely citing it as a justification for either their conclusions or predictions, though older participants were still more likely to cite it.

The lack of major differences between conditions was an unexpected outcome. We had anticipated that the two different ways of framing the data would lead to different theoretical explanations of the data. However, most of the justifications offered for drawing conclusions from the data were based on the numerical evidence (e.g., a trend in the data, sample size), while very few were linked to mechanistic explanations such as a feature of the ball that might cause the outcome. There was a small but significant trend for those in the athlete condition to be more likely to justify their explanations and predictions by suggesting that the athletes may have varied in some way. However, a minority of participants at all age levels used such theoretical justifications. Some researchers have argued that children mistakenly justify conclusions that should be based on data by using their background theoretical knowledge (e.g., Kuhn, et al., 1995). In contrast, we suggest that in fact when children do not have background knowledge upon which to rely, they are likely to talk about the data in justifying conclusions.

In making distance predictions, overestimation was more common than underestimation, particularly among the youngest children. Similarly, third graders often claimed to be totally sure of conclusions they could draw after seeing only one pair of data, while college students tended to reserve their enthusiasm until seeing at least four consistent pairs of data. In general it appears that third graders often overestimate both their confidence in their ability to judge the quality of evidence, and their predictions of future performance. College students were very skilled at basing predictions of future events on the mean of observed events.

This study is a first step toward a clearer understanding of the many factors that influence the use of data in different contexts. Many other data manipulations could be examined to explore this question more thoroughly. For example, one could manipulate the size of within-column variation, the relative size of outliers, and the size of the means. In addition, one could consider multiple groups of data or a single set of data to be evaluated.

Our long-term goal is to better understand the interaction between features of data and theoretical framing, as people of all ages most often encounter data in contexts in which they have some background knowledge. This study was designed to tease apart some of the specific features of data that are used when there is not a lot of theoretical background knowledge influencing conclusions drawn. Future studies will continue to examine different characteristics of data within a range of contexts, to learn more about how they interact to affect reasoning.

Acknowledgments

This research was funded in part by grants to David Klahr from the McDonnell Foundation and from NIH. We owe many thanks to Anne Siegel and Jen Schnakenberg for assistance with data collection, data entry, and draft comments. Thanks also to David Klahr and three anonymous reviewers for comments on an earlier version of this paper.

Abstract

Current computational modeling of human performance can benefit from reusable building blocks of human behavior. Using CPM-GOMS, a cognitively-based task analysis method used in HCI, we have been exploring the concept of reusable templates of common behaviors and their efficacy for generating zero-parameter *a priori* predictions of complex human behavior. This paper details the features we believe are important when moving from hand-crafted models of particular tasks to reusable building blocks of commonly occurring behavior. As this becomes common practice, proportionately more attention can be paid to the task analysis specific to each new domain.

Introduction

To model human behavior successfully one needs to be able to decompose a complex task into a set of primitive operations to which performance parameters may be assigned. These primitives represent the building blocks from which behavior will be constructed such that performance can be predicted for entire task sequences. Thus, the choice of primitives and the method of combining them to construct larger behavior sequences are critical if performance estimates are to be at all accurate. In this paper, we describe a method for combining basic cognitive, perceptual and motor operations into larger behavioral units. These larger units, which will be referred to as *templates*, are applications of psychological theory about the perceptual, motor and cognitive process underlying human performance. Two main points will be argued: 1) task-level reuse is important and 2) behavioral templates are a good way to achieve this reuse. We will present data for a simple HCI task and describe the templates we borrowed (reused) to model it.

Model reuse is a profitable avenue to explore for four reasons. First, consider mousing to a button and clicking on it as an example. People learn and use this skill in most interactions with computers. A model of mousing and clicking on a button should be applicable to many HCI tasks; a new model of mousing and clicking on a button should not be built from scratch for each new task. Second, reuse provides expertise beyond

a single researcher. That is, the model for mousing and clicking on a button can be built by researchers with expertise on visual/motor behaviors and the complex model-builder can benefit from that expertise. Third, reuse provides external verification of the component models. If the model for mousing and clicking on a button predicts the behavior well in the context of a complex task, the data provides an independent test of the mechanisms of that model. Finally, reuse provides additional constraint on models of complex tasks. If the mousing and clicking on a button model predicts the behavior well, the HCI modeler should not change the basic mechanisms of the model simply to make it work in a new domain.

Cognitive architectures such as ACT-R (Anderson & Lebiere, 1998) and Soar (Newell, 1990) embody a large set of reusable constraints on behavior prediction. These, however, are mostly at the cognitive level rather than at a task level. We know how to reuse architectures but not content. Modeling performance on human-computer interaction (HCI) tasks is valuable but currently suffers from several problems. Models of task performance need to be handcrafted and typically take a long time to be created. Neither whole models nor their component parts tend to be reused, allowing little transfer of code from one task model to the next. It is difficult to incorporate psychological knowledge into models and cognitive/psychological expertise is needed to do so. Once a model is complete, it may be uninformative with respect to a next attempt at modeling.

Other disciplines that build complex systems, like engineering and computer science, have successfully employed reuse as an approach to tame complexity and this is an approach that cognitive science should explore as well. There have been numerous arguments about the benefits of using a unified cognitive architecture to provide power, structure and constraint (e.g., Anderson, 1983; John & Altmann, 1999; Newell, 1990), but fewer efforts to incorporate previously-built models of generalized capabilities into models of more complex tasks (e.g., Nelson, Lehman & John, 1994).

Cognitive Modeling Methods

Cognitive architectures such as ACT-R and Soar have attempted to solve some of these problems. Underlying mechanisms embody the psychological theories of the architectures, and so the theories do not have to be explicitly coded for each model. Attempts have been made to reuse models at the task level, but in general this is not a widely adopted practice (e.g., John & Lallement, 2000; Nelson, Lehman & John, 1994). As a result, models are mostly handcrafted and take a long time to create.

The field HCI uses cognitive models in several ways. It often is less interested in the process of modeling than in getting results quickly, and has therefore put emphasis on modeling frameworks that are easier to learn and use than the more complex cognitive architectures like Soar and ACT-R (John, 1998). In addition, that field has sought modeling procedures that reuse actual pieces of models as well as the framework. For instance, GOMS models (Card, Moran & Newell, 1983) are constructed by hierarchical goal decomposition with reusable, empirically-determined execution times assigned to particular goals.

The GOMS methodology has proven highly successful in predicting task completion times for skilled users in routine human computer interaction (HCI) tasks (e.g., Gray, John, & Atwood, 1993; John, Vera, & Newell, 1994). GOMS is really a family of analysis techniques in which performance predictions emerge by combining a task decomposition with estimates of completion times for steps in the decomposition. The task decomposition produces a representation of the task as a set of nested goal states that include an initial state and a final goal state. The user is assumed to move from one goal state to another by applying operators that represent actions, such as moving a mouse or reading a word. The set of nested goal states often resembles a hierarchy, but need not form a strict hierarchy. The iterative decomposition into goals and nested subgoals can terminate in leaf nodes (primitives) of any desired granularity, the choice of level of detail dependent on the predictions required. Times are assigned to the operators that transition between goal states, with additional times often assigned to subgoal completion (Kieras, 1994). Since GOMS is meant to model routine behavior, the user is assumed to have methods that apply sequences of operators and subgoals to achieve a goal. Selection rules are applied when there is more than one method to achieve a goal.

The CPM-GOMS extension to GOMS (John, 1990) adds psychological knowledge to the GOMS goal decomposition by expressing common HCI tasks (e.g. reading from a screen, typing) as patterns of Model Human Processor (MHP; Card, Moran & Newell, 1983) operations of its cognitive, perceptual, and motor processors. These patterns, or templates, can help cognitive modeling by grouping psychological

knowledge into reusable chunks that can be organized into larger behavioral sequences. Although approaching modeling with reusable templates has been taught for a decade (John & Gray, 1992), it has not become widespread, possibly because CPM-GOMS was not in computational form (it had to be done by hand by drawing PERT charts) until recently (John, Vera, Matessa, Freed & Remington, 2002).

Template Structure

Templates are reusable applications of psychological theory that describe short behavioral sequences. Thirteen templates were offered to CPM-GOMS modelers in tutorials and classes in the early 1990s (John & Gray, 1992) and others have been added since then. One example of a CPM-GOMS template for mouse clicking (created by Gray & Boehm-Davis, 2000) can be seen in Figure 1. The template incorporates a psychological theory of the cognitive, perceptual, and motor components of mouse clicking and dependencies between these components. The template was developed in the context of a simple task of clicking on lit circles, but has successfully been reused in the context of clicking to operate a simulation of an automated teller machine (John, et al., 2002).

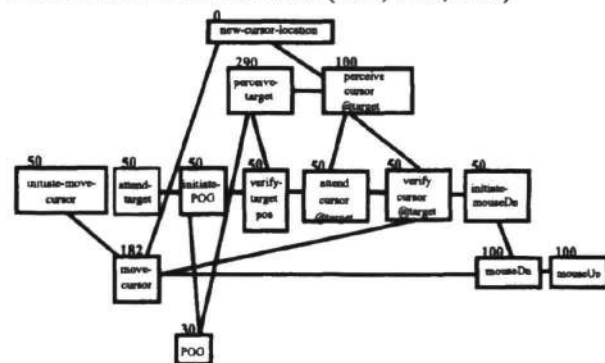

Figure 1: Model of carefully moving the cursor to a target and clicking the mouse button (adapted from Gray & Boehm-Davis, 2000).

The psychology in this template is in the form of the durations, the cognitive bottleneck, the logical dependencies, and the task dependencies. The *durations* for the cognitive, perceptual, and motor components of the template are empirically derived MHP-level estimates of these activities. CPM-GOMS assumes a *cognitive bottleneck*, where cognitive processes cannot execute in parallel. The cognitive resource stream is therefore serially scheduled based on the logical and task dependencies as described below.

According to CPM-GOMS, each motor activity must be preceded by a cognitive activity that initiates it. This is an example of a *logical dependency* — a motor action cannot take place unless a cognitive motor initiation activity has occurred. That you cannot click on a target

until you have moused over to it is an example of a *task dependency*. It is not a CPM-GOMS level logical dependency nor is it a necessary consequence of the cognitive bottleneck; it is true because the task requires it to be so. So, for example, a possible performance error might be to click before the mousing movement to the target is complete. In contrast, executing a motor action without a preceding cognitive initiation is not a possible performance error. Similarly, executing two cognitive activities in parallel is not a possible performance error. This combination of constraints embodies the unique application of psychological theory to the crafting of each template.

Interleaving Templates

Embodying psychological theory in separate templates is only the first step. The challenge is that CPM-GOMS templates need to be interleaved to fully capture the time course of behavior. Simply adding up the performance time predicted by a sequence of templates produces a time that is longer than that of human performance. A key CPM-GOMS assumption is that humans are able to perform certain components of the templates not in strict sequence but interleaved so that some components of a later template can occur in an earlier template.

A concrete example of this interleaving can be seen in a task as simple as hand-washing. While most eye fixations are related to immediate actions such as turning on the faucet, a small number are made to objects relevant only to future actions. Pelz and Canosa (2001), with the aid of an eye tracker, observed that subjects consistently made eye movements to the towel during earlier parts of the hand-washing process.

Part of the psychological theory embedded in templates is the knowledge of what components of one template can occur in parallel with components of another template. This interleaving theory has until recently only been implemented in paper-and-pencil. Details of how interleaving is implemented in our system are presented later. When cognitive components have a dependency on perceptual or motor components which take a relatively long time to complete, slack time may occur when the cognitive resource is not being used. Interleaving involves filling up this slack time with activity from the cognitive components of the next template.

ATM Study & Data

CPM-GOMS has been demonstrated to make accurate zero-parameter *a priori* predictions of skilled HCI behavior. Using templates, we created a CPM-GOMS model of a simple HCI task — withdrawing money from an ATM. We gave two users extensive practice with this task because CPM-GOMS models are expected to predict the performance of highly-skilled users (Baskin & John, 1998).

The ATM Task

The task was to make an \$80 withdraw from a checking account on a Visual Basic simulation of an automated teller machine. Users interacted with the ATM by using a mouse to click on simulated keys or slots. The users were instructed to follow the following steps:

- Insert card (click on the picture of the card slot)
- Enter PIN (click on the 4, 9, 0, and 1 buttons in turn)
- Press OK (click on OK button)
- Select transaction type (click on withdraw button)
- Select account (click on checking button)
- Enter amount (click on 8 and 0 buttons)
- Select correct/not correct (click on correct button)
- Take cash (click on the picture of the cash slot)
- Select another transaction (click on No button)
- Take card (click on the picture of the card slot)
- Take receipt (click on the picture of the cash slot)

This task was repeated 200 times by the users. This level of practice is comparable to that used by both Card, Moran, and Newell (1983) in a text editing task and Baskin and John (1998) in a CAD drawing task when they explored the effects of extensive practice on match to various GOMS models.

Figure 2: Click times for users and models

The CPM-GOMS Model

The CPM-GOMS model was created by first expressing the hierarchical goal structure of the ATM task. At the bottom of the hierarchy were two CPM-GOMS templates: Slow-Move-Click and Fast-Move-Click. The cognitive, perceptual, and motor components of these templates were taken directly from Gray and Boehm-Davis (2000) where predictions from these templates were compared to data from several variations of a simple target selection task.

The Slow-Move-Click template is shown in PERT chart form in Figure 1. Because there was uncertainty about where a target would appear in each trial, Gray and Boehm-Davis considered Slow-Move-Click to represent a careful selection of a visible target. Fast-

Move-Click represented a more confident selection of a target when the user knew where the target was to appear. In our model, we choose to use Fast-Move-Click for clicking on the ATM buttons because they were a reasonable size and Slow-Move-Click for clicking on the card and cash slots because these slots were thinner and difficult to hit unless the user was careful.

Comparing the Model to Data

Figure 2 shows a comparison of the CPM-GOMS model predictions of mouse click times and mean user click times. Because Baskin and John (1998) have found that CPM-GOMS models predict behavior well at around the 100th trial of a practiced procedure, the means of trials 91-100 for each ATM user are shown. To see the benefit of interleaved templates, predictions from two other models are also shown: a model using only Fitts's Law predictions (a motor time prediction based only on target geometry), and the CPM-GOMS model with sequential templates but no interleaving.

The first thing to notice is the good *a priori* fit of the model to user data. The degree to which interleaving contributes to this fit can be seen by comparing the interleaving and non-interleaving models. The *non-interleaving model* generally predicts a longer time for a mouse click and does not capture the variation of user click times. This variation is better captured by the *Fitts's Law only* model, but the model does not represent the perceptual and cognitive processes incorporated into templates and so predicts faster click times than users produce. These comparisons show that templates contain important predictions of perceptual, cognitive, and motor processes, and that the theory of template interleaving can capture the abilities of users to save time by performing parallel processes.

The important point to emphasize is that the templates used to make these predictions were developed for a very different task and were successfully reused in the present model. Also, note that the tool we have developed to implement CPM-GOMS, Apex (Freed, 1998b, Freed & Remington, 2000), allows us to easily generate alternative versions of the model (e.g., just Fitts's Law, templates with no interleaving). We will expand on the workings of the tool below.

Implementing Templates

How does an organism organize its resource allocation over an extended period of time over an extensive sequence of behaviors? Hierarchical task decomposition is a convenient formalism for an analyst to record and communicate their analysis of a task but it also seems to have some psychological reality in how people organize their environment and cognitive resources to approach a complex task. Many representations of human behavior use hierarchical task decomposition, from Scientific Management at the turn of the century, to HTA (Kirwan and Ainsworth, 1992)

to GOMS, Soar and ACT-R. However, in these latter architectures, the hierarchical task decomposition bottoms out at the level of operations of the underlying cognitive, perceptual and motor processors.

It is relatively easy to perform a hierarchical task analysis for each new task domain, and necessary because each domain has its own objects, tasks, knowledge, and procedures. It is much more difficult to describe the cognitive, motor, and perceptual processes underlying every new task. However, many tasks bottom out at the same component behaviors constrained by human abilities. The component behaviors are actions like visual search, mouse movements, and typing. These types of actions are perfect candidates for re-use because they occur repeatedly in many tasks, and must be realized in operations closer to the architecture than is necessary to describe the task domain. Removing the burden of understanding and programming in the underlying cognitive architecture in the form of reusable templates could make cognitive modeling more accessible to a wider range of domain experts.

What does it take to create templates in a cognitive architecture?

- A systematic relationship between the bottom level of the hierarchical task decomposition, the templates, and their realization in the underlying architecture
- A systematic relationship at the boundaries between templates realized in the underlying architecture. This may be more complicated than simple serial execution, as we will describe in the context of CPM-GOMS, the Model Human Processor, and its embodiment in Apex.

Template Grain Size

Generalizable behavior templates should exist at different grain sizes. From a practical modeling perspective, it is valuable to represent basic HCI behaviors in different size chunks. For example, one branch of a hierarchical goal decomposition may terminate at simply clicking on an item whereas another might terminate at a more complex action such as choosing an item from a pull-down menu. The latter action encompasses the first (twice, in fact), but both are useful as separate templates. Along with generalizability, a valuable constraint on the grain size of templates is the level at which hierarchical goal decomposition would bottom out. For example, a template that is just the reaching component of typing a key (i.e., putting your finger over it without pressing on it) would be very general; it would be Fitts's Law plus the associated cognitive and perceptual components. However, it would not typically be where a hierarchical goal decomposition would bottom out. A hierarchical goal decomposition is more likely to bottom out with activities such as click-on-button or press-key than just

the reaching component of these activities, and templates should reflect this.

Implementing Interleaving

The template-builder gets to deliberately program these dependencies. The relationship between templates in CPM-GOMS involves not sequencing, but interleaving of parallel operators on multiple resources. In highly skilled behavior, people attain a high degree of parallelism in their behavior. To illustrate this point, think about printing a document in the word processor you regularly use. It is not uncommon for people to select the Print command then move the mouse to the place where the OK button will appear well before the dialog box is visible. A hierarchical task analysis would list the steps (1) select Print, (2) wait for dialog box, and (3) click on OK, but the realization in the underlying architecture should allow the mouse movement associated with step (3) to precede the completion of step (2), whereas the clicking associated with step (3) must indeed wait for the completion of step (2) or the task will not be successfully completed. Thus, the relationship between templates is a complex system of interleaving of the architectural-level operations.

Apex allows manipulation of serial and parallel resource in exactly the form required by CPM-GOMS. Apex (Freed, 1998a) has a flexible resource management system that allowed the implementation of the constraints necessary to produce CPM-GOMS template interleaving. A complete description of the implementational rules guiding interleaving in CPM-GOMS as embodied in Apex is available elsewhere (Berkovich & Kwong, 2002; John et al., 2002). In general, we use three facets of the Apex architecture:

1. resource modules (i.e., cognition, hands, point of gaze, visual perception),
2. priorities on the templates, and
3. virtual resources to record a template's intention to use a resource.

Resource modules. To accomplish templates, operators consume resources at the architectural level. The resource modules act serially within themselves, so when they are occupied by an operator, other operators that require that resource must wait until that resource is free again. When more than one operator requires the same resource at one time, there needs to be a way to resolve the conflict and assign that resource to only one operator. Within a template, such conflicts are either avoided because of logical dependencies between the operators (e.g., perceiving a target cannot happen until the eyes have moved to that target) or resolved randomly because the template-builder has determined that it does not matter for the completion of the task whether one goes before the other. When there is contention for resources between operators in different templates, an additional mechanism for conflict resolution is needed.

Priorities. When there is competition for a resource between templates, priorities of the templates is used. Each template is assigned a priority associated with its order in the hierarchical task decomposition. In the printing example above, selecting the Print command (step 1) has the highest priority, waiting for the dialog box (step 2) has the next highest priority, and clicking the OK button (step 3) has the lowest priority. Both steps 1 and 3 will contend for the right hand to move the mouse to their respective targets, and step 1 will win by its priority, ensuring that the print command is selected before the mouse is moved to where the OK button will appear. However, step 2 (waiting) does not require the right hand, so the mouse is free to move to the location of the OK button before the dialog box appears.

Virtual resources. However, resources and priorities are not enough. For instance, the template to select the print command (step 1) requires the eyes to move to and perceive the menu title, and later within the same template to move to and perceive the desired menu item. However, while the hand is completing the move and click to the menu title and the menu is coming up, the eye resource is free. Therefore, step 3, clicking on the OK button wants the eye to move to the location of the OK button, and since the resource is free, there is no contention and priorities do not come into play. Thus, the eye resource could be assigned to the OK button even though the menu item will be appearing in a fraction of a second and the eye will be needed there. Therefore, to reserve the eye for the higher-priority template (in this case, the select-menu-item(Print)), we developed the idea of virtual resources. Virtual resources are analyst-defined entities that act like regular resources. Operators consume these resources and they have to be allocated using priorities. So at the beginning of the select-menu-item (Print) template's first eye movement, it reserves the eye-block virtual resource and only releases that virtual resource after its last visual perception is complete. Since all eye-movements and visual perception require this eye-block virtual resource, this technique blocks any lower-priority template from stealing that resource before a higher-priority template is finished with it.

Discussion

We have a computational system that implements and automatically interleaves reusable behavioral templates. While only two templates have been presented here in detail (Slow-Move-Click and Fast-Move-Click), several others have been implemented in our system for touch-typing and applied to a different computer aided design task, and several more are under development for interacting with the flight maintenance system found on commercial airliners. Previous work has shown that other currently existing templates in the literature are useful for simulations done by hand (Gray, John, &

Atwood, (1993) being a good example). We will work to implement these as well. As more templates are accumulated, issues such as coverage of possible behaviors can be addressed.

We are currently exploring the possibility of generating CPM-GOMS models from ACT-RPM. ACT-RPM imposes its own set of constraints on cognitive, perceptual and motor resources, many of them different from those of CPM-GOMS. This makes the generation of genuine CPM-GOMS behavior from ACT-RPM more challenging but also promises the possibility of extending the predictive scope of CPM-GOMS to a wider range of skill (i.e., from novice to expert) because of ACT-R's new production compilation mechanism (Taatgen & Lee, submitted)

In order for cognitive modeling to come into wider use in the design process, it is necessary to package the abundance of data on human perceptual, cognitive, and motor phenomena into a set of behavioral templates that can be directly incorporated into predictive, computational models. Templates reduce the amount of psychology and modeling methodology required to build models, compile the human performance data into templates, and allow the modeler to focus on task analysis.

Abstract

Collaborative problem solving involves the active exchange and interaction of ideas between two or more people and such interactive exchanges can result in the joint production of co-constructed ideas, some of which may be novel. We analyzed verbal data of pairs of students collaboratively solving problems posed by a computer workplace simulation (a banking business), and then individually solving two transfer problems, in order to examine the frequency of occurrence of co-constructed novel ideas, and the subsequent individual reuse of these co-constructed ideas. The results show that in collaborative interactions, about 20% of the task-relevant ideas were produced jointly, whereas about 80% of the utterances were produced individually (i.e., they were self-explanations). However, about half of these jointly produced ideas (or 10%) were novel. Moreover, individual collaborators were able to reuse these jointly constructed ideas to solve transfer problems. Finally, more interactive collaborative pairs produced a higher proportion of jointly constructed ideas than less interactive pairs, and individual members of more interactive pairs reused jointly constructed ideas more than low interactive pairs.

Introduction

In classrooms and workplaces, individuals frequently learn by collaborating with others, in tasks such as solving physics problem (Kneser & Plotzner, 2001), planning (Barron, 2000), and learning electricity (van Boxtel, van der Linden, & Kanselaar, 2000). Although operational definitions of collaboration vary widely both within and across various fields (e.g., Psychology, Education, Artificial Intelligence, CSCL), for the purposes of this paper, we define collaboration as the active exchange and interaction of ideas between two or more individuals attempting to discover solutions or create knowledge together (Damon, 1984). While some of the results of previous collaboration research are inconsistent, the majority support the conclusion that compared to solving a problem alone, collaborative problem solving is often more efficient, and in some conditions, more efficacious than individual learning (SCANS, 1991; Webb & Palinscar, 1996).

Most of the initial research on collaborative learning focused on the environmental conditions under which collaborative learning was more effective than individual learning. Some examples of such environmental factors are group composition, task features, context, and communicative medium (Dillenbourg et al., 1996). However, these mediating factors also interact in a highly complex manner, and this complexity has made the resulting examination of

this complexity has made the resulting examination of how these multiple interactions produce collaborative learning effects a very difficult pursuit.

In part due to this difficulty, an alternative approach to the study of collaboration focuses on the interactive processes that are thought to underlie successful collaborative learning. Examples of such processes are observing peers' strategies, engaging in productive argumentation, explaining one's own thinking, sharing knowledge, and providing critique (Azmitia, 1988; Bos, 1937; Coleman, 1998; Hatano & Iganaki, 1991; King, 1990; Phelps & Damon, 1989; Webb, Troper, & Fall, 1995). Many of these processes are captured more-or-less in Webb & Palinscar's (1996) 'Input-Process-Output' model of group (collaborative) processes.

The process component of the model contains four common collaborative learning processes: (a) resolving conflict and controversy, (b) giving and receiving explanations, (c) providing emotional and motivational support, and (d) co-constructing new ideas. The first two processes result in the generation of explanations, either to resolve a conflict, or to explain a problem or solution, and such explanation generation is known to produce learning gains (Chi, Bassok, Lewis, Reimann, & Glaser, 1989; Palinscar & Brown, 1984). The third process is generally comprised of personality factors (e.g., emotion regulation, motivation, social skills, and attitudes), each of which effects how collaborators interact with one another. The fourth process, co-construction, can potentially result in novel ideas, or ideas that no collaborator previously possessed explicitly.

While Webb & Palinscar's (1996) four collaborative processes do drive collaborative learning effects, the first three processes are not unique to collaboration -- that is, each can also be observed and implemented in individual learning environments. For example, conflict and controversy can arise within oneself when one thinks more deeply about, or attempts to integrate new information with, one's prior beliefs. The resolution of such conflict (or self-repairs) produces learning gains (Chi, 2000). Similarly, giving help or explanation is akin to self-explaining one's own thinking without interacting with another individual, and such self-explanations foster learning (Chi et al., 1989). Similarly, receiving explanations has always been shown to be helpful as well, but less so than giving explanations. Providing emotional and motivational support is also not unique to collaboration -- individuals are capable of supporting their

own emotional and motivational needs. In the end, while all four of Webb & Palinscar's (1996) proposed collaborative processes do drive collaborative learning effects, co-construction is the only one that is unique to collaborative learning.

Co-construction has been defined as the process of the joint production of ideas (by members of a group) that no individual group member is likely to produce on their own (Barron, 2000; Rafal, 1996). Thus, co-construction is a process that may differentiate collaborative and individual learning environments. That is, collaborators may co-create novel ideas that were not coherently present before they collaborated, or were unlikely to have been elaborated individually. For example, Kneser and Ploetzner (2001) administered qualitative and quantitative pre-test, intermediate-test, and post-test questions to individuals learning mechanics. One group of students was instructed on how to solve mechanics problems qualitatively, while another group was instructed quantitatively. After administering the intermediate-test, individuals from the two contrasting groups were placed in dyads and asked to collaboratively solve new mechanics problems. The authors found that individuals were able to answer questions (post-test) that they were unable to answer prior to collaborating (intermediate-test). However, the results of this study must be interpreted cautiously since the pairs differed in expertise, which suggests that one member of the dyad may have learned from the other member, and not that the dyads co-constructed the answers together.

Hence, the goals of this paper are to document the extent to which collaboration facilitates the joint production of novel ideas, and the extent to which individual members of collaborating pairs take ownership of jointly produced novel ideas such that they are able to assimilate and reuse those ideas later in individual (transfer) situations. To address these questions, we report a detailed verbal analysis of collaborative protocols collected in the context of dyads interacting with a computer simulation.

Methods

The verbal data that we analyzed were collected and described in Jeong, Taylor, and Chi (2000). Here we briefly summarize how the verbal data were collected and the measures that are relevant to our analysis.

Participants

Twenty-six high school students (juniors and seniors from local urban high schools) participated in this study, comprising 13 collaborative pairs (4 male and 9 female same-sex collaborative pairs). Data from one pair was excluded from analysis due to a collection error, resulting in 12 collaborative pairs. Individual participants brought a friend of the same gender to participate in the study with them, resulting in pairs where each collaborator had known the other for a mean of 4 years. All participants were compensated for participation in the study and all reported familiarity with com-

puters. A majority of the students reported that they had used other computer simulations or games in the past.

Materials

Court Square Community Bank (CSCB). CSCB is a computerized workplace simulation (SIM) in which the user assumes the role of a new vice-president at a small local bank. The VP is required to solve problems arising at the bank that cover a variety of general business issues such as facilities upgrades or customer relations. The problems encourage the VP to employ a number of business management activities (see Ferrari, Taylor, and VanLehn, 1999; and McQuaide, Leinhardt, & Stainton, 1999; for more details on the simulation program). We will use the more general term SIM to refer to CSCB.

SIM Problems. The SIM is sub-divided into 14 different episodes, 8 of which were selected for this study so that diverse topics would be covered with a minimum amount of overlap. Sample episode topics were reinvesting profits into bank facilities, closing/relocating branches, approving mortgages, and selecting the best candidate for a position.

Measures. Several measures, such as definitions and general business knowledge questions, were designed to assess participants' overall pre-test and post-test performance. The one relevant here is the transfer task that assessed general and context-specific knowledge at a deeper level than the definitions and questions measures.

The transfer task consisted of two problems (Fresh Foods and Giant Gallery), each modeled after two problems discussed in two SIM episodes (episode 9 and 10). The transfer problems were designed to appear different on the surface, but shared the same deep structure as the associated SIM problems. During the transfer problems, participants acted as vice-president (VP) of a grocery store company that experiences some of the same problems that the bank experienced in the SIM. In the Fresh Foods problem, students decided how to allot available funds to various facilities improvement options for the grocery store – as they did for the bank in SIM episode 9. In the Giant Gallery problem, students decided whether to close a less profitable store and/or open a new store – as they did for bank branches in SIM episode 10.

Talk-aloud protocols were elicited from participants to obtain more detailed performance data. Participants were instructed to talk-aloud (Ericsson & Simon, 1984) during their collaborative (simulation) and individual (transfer) problem-solving sessions, both of which were audiotaped. All collaborative SIM sessions were also video-taped.

Procedure

Participants took part in four laboratory sessions, each separated by approximately four days, in the following order: (1) pre-test, (2) simulation session I, (3) simulation session II, and (4) post-test.

The pre-test and post-test were administered to participants individually, and both tests asked participants to respond to the definitions, transfer, and questions tasks – and in that order. Each simulation session consisted of four epi-

sodes. The first three episodes in each session were performed collaboratively in dyads, and the last problem in each session was performed individually. On the collaborative problems, the pairs were instructed to work as a team in discussing how to handle the problems and to reach a consensus before making any decisions.

Analyses and Results

We report the results of verbal analyses (Chi, 1997) of individuals' performance on the two transfer problems and their associated SIM episodes 9 and 10. This section describes each step of verbal analysis employed, followed by its result.

The Number of Task-relevant Ideas

Did collaborators produce task-relevant ideas? To assess the number of task-relevant ideas the pairs articulated, each pairs' verbal protocols were coded for any combination of utterances representing a meaningful concept. Hence, ideas could be produced either by one individual in one turn, by one individual over several conversational turns, or by both individuals over several turns on one topic. Ideas were also required to be task-relevant – that is, related either to business in general, the theme of the episode (i.e., facilities improvement), or a solution the pair considered. Task irrelevant ideas consisted of comments of several types, such as “I guess you just gotta ask”, “We need to find out some more information”, or “Read the memo”, and they were not coded.

Example 1 shows an articulated task-relevant idea. Note that examples are verbatim excerpts from protocols with prior utterances (in brackets) added for additional context.

Example 1: Articulated Idea

A: [If we renovate the floors] we will not be able- [to maintain our leadership because...]

B: [subjects speaking simultaneously] new technology.

A: Exactly...because we will not have the new technology.

The basic idea expressed in example 1 is that renovating the floors will consume the majority of the funds available for facilities improvements, resulting in a lack of funds available to purchase new technology (ATMs) that would help the bank maintain its leadership position in the marketplace.

In general, the protocols were sparse in terms of the amount of substantive ideas produced. For example, the total number of lines available to code from two randomly chosen pairs were 2,131 and 1,320 (pairs 8 and 11, respectively, episode 9). Of those lines, only 3% and 1%, respectively, were substantive enough to warrant coding. This is consistent with evidence in the literature showing that in collaborative tasks in which concrete actions have to be taken (such as working with a simulation), the dialogues are action-oriented and less abstract and rich (Bennet & Duane, 1991; Pilkington & Parker Jones, 1996; van Boxtel et al.,

2000) Nonetheless, in playing the two episodes of the simulation, collaborative pairs produced a total of 365 task relevant ideas ($M=30.42$, $SD=9.23$, per pair). The remaining analyses will be reported in the context of the total number of task relevant ideas.

The Number of Novel and Restated Ideas

Were the task-relevant ideas produced while playing the two simulation episodes novel or restated? To assess whether collaborators generated novel constructions, as opposed to merely restating information presented by the SIM, we compared the ideas produced by collaborators to the ideas explicitly presented by the SIM (SIM-ideas). SIM-ideas were identified through content analysis of the two relevant SIM episodes (9 and 10). This content analysis produced a transcript of the virtual conversations, interactions, and materials explicitly presented by the SIM. SIM-ideas were then identified in the SIM-transcripts following the same procedure employed to identify collaborative ideas. We then compared the collaborative ideas produced by a pair to the SIM-ideas that they were exposed to in order to determine whether the collaboration idea was a novel construction (no match), or a restatement of information embedded within the simulation (match). When comparing ideas we focused on their conceptual meaning rather than the literal vocabulary used.

Ideas coded as novel constructions were new reasons generated by students (most likely from prior knowledge or experience), inferences following from what was stated in the SIM episode, substantial paraphrases (paraphrases of more than one idea), and integration statements in which students combined ideas expressed in the SIM episode in ways that the SIM did not explicitly suggest. Restated ideas were unsubstantial paraphrases (one idea), or verbatim restatements of information presented by the SIM. Examples of a novel construction and a restated idea are given below:

Example 2: A Novel Construction (also jointly produced)

B: This proposal [New ATMs] helps the bank's profitability

A: help

B: helping the bank to run

A: more smoothly

Example 2 was coded as a novel construction because the SIM never explicitly relates the bank's profitability with new ATMs or with the bank running smoothly. (Note that example 2 is also a jointly produced idea, which will be described in the next section).

Example 3: A Restated Idea

B: [New ATM] cards will be easier to use

SIM: New ATMs are easier for the customer to use.

Example 3 was coded as a restated idea because what B articulates is an unsubstantial paraphrase of the SIM articulated idea that new ATMs are easier to use. The results of

this analysis show that collaborators produced just as many novel ideas (197) as restated ideas (168).

Individually and Jointly Constructed Ideas

Given that many novel ideas were produced, the question of interest is whether they were jointly produced (i.e., co-constructed), or individually produced, as compared to restated ideas. Thus, for each of the 197 novel and 168 restated ideas we determined whether they were individually constructed or jointly co-constructed. Co-constructed ideas were defined as those ideas that when taken together, across speakers, form a complete idea, but when taken individually, do not represent the same complete idea (Rafal, 1996; Barron, 2000). Thus, we decomposed each idea unit into 3 component parts: initiation, elaboration, and completion. Initiation was defined as the point at which the first utterance (word) of the idea occurred; completion was defined as the point at which a meaningful statement could be identified; and elaboration was defined as the collection of utterances between initiation and completion, where the content of the idea was articulated. We then examined how each idea was produced in terms of who articulated each component.

For each idea, if the same collaborator produced all three components, then the idea was coded as individually produced. Alternatively, if different collaborators produced any of the components of one idea, then that idea was coded as jointly produced. Hence, jointly produced ideas required the collaborators to display conversational moves such that they completed each other's ideas. The following examples illustrate this.

Example 4: An Individually Produced Idea

- A: revenues and expenses at the downtown branch changed
 B: Uhh...
 A: revenues have just start like increase and decrease and then leveled off so...
 B: Umm...yeah... [typing] how do you spell fluctuate
 A: fluctuating, but now it's leveled off and...
 B: How do you spell...
 A: well, they generally decreased

Example 4 shows a complete idea (revenues and expenses fluctuated but decreased in general) initiated, elaborated, and completed by one collaborator (A), while the other (B) interjects task-irrelevant utterances. The initiation component in this case is the beginning of the statement: "revenues..." the completion component is the point at which a complete idea is identifiable: "...generally decreased"; while the elaboration component is the content between the initiation and the completion of the idea.

Example 5: A Jointly Produced Idea:

- B: Okay, the new system would give the- give the employees...
 A: more time to deal with the customers.

Example 5 shows an idea (of a new system) initiated by one collaborator (B), then elaborated and completed by the other collaborator (A). Example 2 also illustrates a jointly-produced idea.

Table 1 shows the number of novel and restated ideas that were either individually or jointly produced. Not surprisingly, roughly four times (81%) as many ideas were individually (297) rather than jointly (19% or 68) produced. Proportionately, jointly produced ideas were just as likely to be novel (59%, 40/68) as restated (41%, 28/68).

Table 1: Total Number of Jointly and Individually Produced, Novel and Restated Ideas for All Collaborative Pairs

	Novel	Restated	
Individually Produced	157	140	297
Jointly Produced	40	28	68
	197	168	365

In sum, collaborative pairs produced ideas jointly about 20% (or 68) of the time; individually about 80% (or 297) of the time. Given that jointly produced ideas were equally likely to be novel as restated, about 10% (or 40/365) of the ideas were jointly produced novel ones.

Reuse of Ideas During Transfer

Did individuals reuse the jointly produced novel ideas on transfer problems? In other words, were the individual collaborators able to reuse the jointly produced novel ideas, to indicate that they have, to some extent, taken ownership of or assimilated the ideas? Each individual idea stated while solving a transfer problem was compared to each idea originally produced by the pair when they solved the associated SIM episodes. If an idea articulated while solving the transfer problem matched one that was produced while playing the SIM, then the idea was coded as a reused idea.

In order to make more sensitive comparisons between collaborative pairs during the SIM and individuals at transfer, each individual's transfer performance was averaged with the individual transfer performance of the other member of their original collaborative pair. This averaging procedure resulted in equal *n* in each condition (collaboration vs. transfer).

In general, the transfer transcripts were sparser than the collaborative transcripts in terms of the total number of ideas produced (114; $M=9.5$, $SD=3.75$). Of these, 32% (36/114) were ideas that were originally produced during their collaborative session. Overall, individual collaborators reused more ideas that were originally produced individually (25) than ideas that were produced jointly (11). However, recall that a significantly greater number of ideas were originally produced individually (297, see Table 1), rather

than jointly (68). Thus, proportionately, a larger percentage of jointly produced ideas were reused (16% or 11/68) than individually produced (8%, or 25/276), although this difference is not significant. Basically, jointly and individually produced ideas were equally likely to be reused.

Not surprisingly, of the individually produced ideas, participants tended to reuse those that they generated on their own (64% of the times, 16/25) more than those that were generated by their partner (36% of the time, 9/25; $t(11) = 2.86, p < .05$). In contrast, in the reuse of jointly produced ideas, there was no preference for self-initiated or partner-initiated (59% or 6.5/11 versus 41%, 4.5/11). Taken together, these results suggest that jointly produced novel ideas were equally shared by each partner, regardless of who initiated them, whereas individually produced ideas were not as well assimilated by the partner.

In sum, these results show that about one-third (32%) of the ideas individuals stated while solving the transfer problems were originally produced during collaboration, and these reused ideas were equally likely to have been individually produced as they were to have been jointly produced. However, collaborators had a definite preference to reuse self-initiated, individually produced ideas, but had no such preference when reusing jointly produced ideas. This gives the jointly produced ideas a special status, as if the ideas were truly shared and owned by both partners.

High and Low Collaborative Pairs

We hypothesized that pairs who were more interactive would produce more co-constructed ideas. To test this hypothesis, we determined whether specific pairs were more or less collaborative based on the number of conversational turns taken by each pair while they solved SIM episodes 9 and 10. High and low collaborative groups were then formed based on a median split ($Mdn = 933$ turns), and excluded two pairs extremely close to the median. The mean number of turns for high and low groups was significantly different (1186.4 vs. 763.8 turns, respectively; $t(8) = 5.171, p < .01$), and there was no significant difference in the total number of ideas produced overall. (Note that from this point forward high and low collaborative pairs will be referred to as such, while individual members of high and low collaborative pairs will be referred to as high and low collaborators).

Once the groups were established, we compared the proportion of ideas produced jointly versus individually by high and low collaborative pairs. For the high collaborative pairs, the proportion of ideas that were jointly produced was greater (27% vs. 9%; $t(8) = 3.77, p < .01$); while the proportion of individually produced ideas was lower (73% vs. 91%, $t(8) = 3.82, p < .01$). Additionally, the proportion of jointly produced and novel ideas was also greater for high collaborative pairs (17% vs. 6%); ($t(8) = 3.10, p < .05$).

In sum, being a member of a high collaborative pair resulted in a redistribution of the types of ideas produced during collaboration. That is, high and low collaborative pairs produced equal numbers of ideas overall, but high collabor-

ative pairs produced more ideas jointly and fewer ideas individually than low collaborative pairs; and high collaborative pairs produced a greater proportion of novel co-constructed ideas than low collaborative pairs.

High and Low Individuals' Reuse of Ideas

While solving the transfer problems alone, individual members of high and low collaborative pairs produced roughly equivalent total numbers of ideas (52 vs. 46.5, respectively), as well as roughly equivalent numbers of reused ideas (19 vs. 13; see Table 2). However, the types of reused ideas were again differentially distributed - high collaborators reused more jointly produced ideas than low collaborators (18% vs. 8%, 8.5/47 vs. 1/12; $t(8) = 2.434, p < .05$), and high collaborators were more likely to reuse jointly produced novel ideas than low collaborators (20% vs. 11%, 5.5/28 vs. 1/9), although this difference was not significant ($p = 0.10$).

In sum, individual members of high collaborative pairs reused more jointly produced ideas, and had a greater tendency to reuse jointly produced novel ideas. Taken together, this pattern of results suggests that if collaborators engage in more interaction then they are more likely to produce co-constructed ideas, these co-constructed ideas are likely to be novel, and both the co-constructed and novel co-constructed ideas are likely to be reused. Hence, collaboration has the advantage of producing co-constructed ideas and co-constructed novel ideas that are reusable.

Table 2: Number of Ideas Reused by Individuals Who Participated in High and Low Collaborative Pairs

	High	Low
Ideas at Transfer	52	46.5
Ideas Reused	19 (36%) ¹	13 (28%) ¹
Individually Produced	10.5 (8%) ²	12 (9%) ²
Jointly Produced	8.5 (18%) ²	1 (8%) ²
Novel Ideas	13.5 (13.5%) ²	7.5 (10%) ²

¹ % of ideas produced at transfer that were reused (e.g., 19/52 = 36%).

² % of ideas reused at transfer given the number produced during collaboration (see Table 1); (e.g., Reused Individually Produced = 10.5; Individually Produced during collaboration = 128; 10.5/128 = 8%).

Discussion

These results suggest that one advantage of collaboration may arise from the co-construction of novel ideas. Overall, we found that collaborators tended to produce more ideas individually than jointly, confirming the overall benefit of self-explaining (Chi, et al, 2000). However, joint production did occur close to 20 percent of the time, and jointly pro-

duced ideas were just as likely to be novel as restated. Overall, more novel ideas were produced individually than jointly (again, confirming the benefit of self-explaining). However, individuals reused fewer novel ideas that were individually produced by their partner than were jointly produced with their partner, suggesting that listening to novel ideas produced by another was not as effective as co-constructing novel ideas together. These results suggest that one does not assimilate knowledge produced by a partner as well as knowledge co-constructed by both partners. Finally, the more interactive collaborators reused a greater percentage of jointly produced ideas, as well as a greater percentage of jointly produced novel ideas, thus being more interactive provided more opportunities to co-construct and reuse novel ideas. Thus, we may conclude, (cautiously since the numbers are small), that collaboration is an effective form of learning in part because about 10% of collaborative efforts result in the production of co-constructed novel ideas, a portion of which individuals take ownership of and reuse subsequently.

A Strong Schema Can Interfere with Learning: The Case of Children's Typical Addition Schema

Nicole M. McNeil (nmmcneil@students.wisc.edu)

Abstract

This study investigated whether children's schema for typical addition interferes with their ability to learn about mathematical equivalence. In a pretest, elementary school children (1) solved a set of math equivalence problems (e.g., $3 + 4 + 5 = 3 + \underline{\quad}$), (2) reconstructed equivalence problems after viewing them briefly, and (3) provided definitions of the equal sign. Children were categorized according to the number of measures (out of 3) on which they exhibited the typical addition schema. Children then received one of four interventions that presented new information about equivalence problems. Finally, children completed a posttest similar to the pretest. From pretest to posttest, children who exhibited the addition schema on all three measures were the least likely to change their strategy for solving the problems, followed by children who exhibited the schema on two or one of the measures. All of the children who did not exhibit the schema on any of the three measures changed. It is important to note that all children used incorrect strategies at pretest, so it was the addition schema in particular that was associated with change resistance. Thus, a strong schema can interfere with learning. Furthermore, children's addition schema may put them at risk for difficulties in learning higher-level mathematics.

Some behaviors and ideas are particularly difficult for individuals to acquire, even after numerous attempts have been made by the individuals to learn them or by instructors to teach them. Consider, for example, a woman who has always counted on her fingers when solving addition problems. She does not wish to count on her fingers; in fact, she finds it to be an infuriating habit. However, no matter how hard she tries to memorize the addition facts, she always seems to resort to counting on her fingers. Consider also a father who is trying to learn a second language as an adult. The father is frustrated because his daughter, who is only five years old, is learning so much more quickly than he is. Why is it so difficult for the woman to memorize the addition facts and for the father to learn a second language? One reason may have to do with the organization and strength of the behaviors and ideas they already possess. The woman's knowledge about

addition may be organized into a strong schema that interferes with her memorizing of the addition facts, and the father's knowledge about his first language may be organized into a strong schema that interferes with his learning of the second language.

A schema can be defined as a higher-level assembly of knowledge that is "unitized" in that it supersedes its constituent parts and acts as a whole (cf. Smolensky, 1986; see also Hayes-Roth, 1977; Hebb, 1949). Once established, schemata can serve as selective mechanisms that determine how environmental stimuli are encoded, interpreted, and stored in memory. In general, schemata enable fast and efficient processing of environmental stimuli. However, this efficiency can come with a price, especially if a particular schema is inaccurate or lacking in some way.

When a schema is strong, it resists change (e.g., Allport, 1954; Bartlett, 1932; Bruner, 1957; Schutzwahl, 1998). Individuals who have a strong schema have been shown to resist learning new information when it is more specific than (Adelson, 1984; Thorndyke & Hayes-Roth, 1979), not applicable to (Voss, Vesonder, & Spilich, 1980), or discrepant with (Marchant, Robinson, Anderson, & Schadewald, 1991; Markus, 1977) their current schema. Indeed, individuals who have a strong schema often actively resist change by modifying or distorting environmental input so that it corresponds to their schema (Bartlett, 1932; Bruner & Postman, 1949; Guion, Flege, Akahane-Yamada, & Pruitt, 2000; Hannigan & Reinitz, 2001). Importantly, the stronger a schema is, the more resistant it is to changing (see Luchins, 1932).

Although the strength of a schema has clear behavioral consequences, it is not always obvious how to operationalize schema strength *a priori*. Some theories suggest that strength may be determined by how practiced particular action procedures are (Luchins, 1942), while others suggest that it may be derived from tightly organized perceptual (Flege, Bohn, & Jang, 1997; Intraub & Bodamer, 1993) or conceptual (Wellman & Gelman, 1992) information. These accounts need not oppose one another, though, because any given schema is likely constructed out of various related sub-schemata (Smolensky, 1986). We propose that schema strength depends on the relationship

between the three knowledge sources (action procedures, perceptual information, and conceptual information). According to this view, the strongest schema is one in which all three knowledge sources converge.

In the current study, we focused on a particular schema that most elementary school children possess. We refer to the schema as the *typical addition schema*. This schema includes action procedures for solving typical addition problems (e.g., $4 + 5 = __$, $9 + 2 + 6 = __$), such as counting up all of the numbers in the problem or summing all of the numbers by retrieving addition facts from memory. It also includes particular perceptual patterns, such as the pattern of having " $= __$ " at the end of problem (Baroody & Ginsburg, 1983). The schema also includes a conceptualization of the equal sign as an operational symbol that means "the total" (Kieran, 1981; Rittle-Johnson & Alibali, 1999). When an addition problem is presented, the typical addition schema can be activated as a whole, enabling fast and accurate processing of the problem (McNeil, 2001).

The typical addition schema is adaptive because children need to use their knowledge of addition to learn other math concepts, such as multiplication and division. However, it may come with a price. Specifically, it may interfere with children's ability to learn about novel mathematics problems, such as mathematical equivalence problems, which are problems that have addends on both sides of the equal sign (e.g., $3 + 4 + 5 = 3 + __$; Perry, Church & Goldin-Meadow, 1988).

Past work has shown that some children have an especially strong typical addition schema that leads them to distort environmental input about mathematical equivalence to correspond to their schema. Consider the problem $3 + 4 + 5 = 3 + __$. In solving this problem, some children add up all the numbers and put 15 in the blank (McNeil & Alibali, 2000). In reconstructing the problem after viewing it briefly, some children reconstruct it in terms of the " $= __$ at end" perceptual pattern and write " $3 + 4 + 5 + 3 = __$ " (McNeil, 2001). In defining the equal sign in the problem, some children say that it means to "add up all the numbers" (McNeil & Alibali, 2002).

Once children gain more experience with or are instructed about mathematical equivalence problems, they are bound to generate new ways of thinking about the problems. However, these new ways of thinking may be in conflict with their already established typical addition schema, and the two may compete for precedence (cf. Siegler, 1999). Accordingly, we hypothesize that the strength of the typical addition schema should be directly related to children's tendency to resist changes in their thinking after an intervention that provides new information about equivalence problems.

Method

Participants

The sample consisted of 67 third-, fourth-, and fifth-grade children (29 boys and 38 girls), all of whom solved a set of mathematical equivalence problems on the experimental pretest incorrectly. Children attended public or parochial schools in the greater Madison, Wisconsin area.

Measures

Problem Solving The problem solving measure elicited action procedures for solving the problems. It consisted of three mathematical equivalence problems of the form $a + b + c = a + __$. For each problem the experimenter placed the problem on an easel and said, "Try to solve the problem as best as you can and then put your answer in the blank." After children wrote a solution, the experimenter said, "Can you tell me how you got x ?" After explaining each solution, children were asked to rate how certain they were about their "way of doing" the problem on a 7-point scale that ranged from "It's definitely wrong" to "It's definitely right," with "I'm not sure if it's wrong or right" as the midpoint.

Problem Reconstruction The problem reconstruction measure elicited perceptual representations of the problems. Two tasks made up the measure. The first was taken from Rittle-Johnson and Alibali (1999). Children were asked to reconstruct three equivalence problems of the form $a + b + c = a + __$ after viewing each for five seconds. The second task also included three problems and was a recognition version of the first task. Children were given a sheet of paper face down with seven problems on it. One of the problems was an equivalence problem in its correct form. The other six problems depicted errors children typically make when reconstructing equivalence problems, one of which was the typical addition foil $a + b + c + a = __$. After viewing an equivalence problem for five seconds, children were instructed to turn the sheet of paper over and find the problem that they just saw.

Equal Sign Definition The equal sign definition measure was used to elicit conceptual understanding of the equal sign. Two tasks made up the measure. Both were taken from Rittle-Johnson and Alibali (1999). Children were first asked to define the equal sign. Then, they were asked to rate the smartness of six fictitious students' definitions as not so smart, kind of smart, or very smart. The definitions were "the answer to the problem," "repeat the numbers," "the end of the problem," "something is equal to another thing," "two amounts are the same," and "the total."

Procedure

Children participated individually in one experimental session that was videotaped. In the pretest, children first completed the problem-solving measure, followed by the problem reconstruction and equal sign definition measures presented in random order. After the pretest, children were randomly assigned to intervention conditions in a 2 (reconstruction intervention or no reconstruction intervention) \times 2 (equal sign definition intervention or no equal sign definition intervention) factorial design. During the intervention, children in all four conditions were presented with an equivalence problem that had the correct solution written in the blank ($3 + 4 + 5 = 3 + \underline{\quad}$). In the control condition, children were shown the correctly solved problem and were told that it was a correctly solved problem. They were then encouraged to think about the problem for one minute. Children in the other three conditions also were presented with the correctly solved problem, were told that it was a correctly solved problem, and were encouraged to think about it. In addition, children who received the reconstruction intervention were encouraged to notice the equal sign in the problem and were asked to point to it. Children who received the equal sign definition intervention were told that the equal sign means "that the things on one side of it have to be the same as the things on the other side of it" and were asked to repeat the definition. All children spent a total of one minute in the intervention. After the intervention, children participated in a posttest in which they first completed the problem reconstruction and equal sign definition measures in random order, followed by the problem-solving measure.

Coding

Problem Solving Problem-solving strategies were coded using a system developed by Perry, Church and Goldin-Meadow (1988). Strategies were assigned based on children's problem solutions and verbal explanations.

Problem Reconstruction Each reconstruction was examined for conceptual errors. Conceptual errors were errors that reflected inaccurate reconstructions of the structure of the equation, such as omitting the equal sign or one of the plus signs. Errors in reconstructing the particular numbers or order of the numbers were not counted as conceptual errors (e.g., for the problem $3 + 4 + 5 = 3 + \underline{\quad}$, writing $4 + 3 + 5 = 3 + \underline{\quad}$). Each recognition response was scored as correct or incorrect based on whether children correctly identified the equivalence problem on the sheet provided.

Equal Sign Definition Definitions were coded as expressing the concept of equivalence or not. None of the children gave a definition that expressed the concept of equivalence on the pretest. Children's ratings of each

of the fictitious student's definitions of the equal sign were coded. Two points were given for "very smart" ratings, one point was given for "kind of smart" ratings, and zero points were given for "not so smart" ratings. The sum of the ratings for the two definitions "the total" and "the answer to the problem" were subtracted from the sum of the ratings for the two definitions "two amounts are the same" and "something is equal to another thing" to yield a difference score. A positive difference score indicates that definitions expressing the concept of equivalence were rated as smarter than definitions such as "the answer" and "the total."

Typical Addition Schema Children were categorized according to whether they exhibited the typical addition schema on the pretest measures. They were coded as exhibiting the schema on the problem-solving measure if they (1) used the "add-all-the-numbers" strategy on at least two of three equivalence problems (as shown in Table 1) and (2) gave that strategy an average certainty rating greater than four (on the 7-point scale). Recall that ratings of less than four indicate children think their strategy is incorrect. Children who use the add-all-the-numbers strategy but rate it as incorrect are likely using the strategy because they cannot come up with any alternatives (see Siegler, 1983), rather than because they are operating according to a strong schema *per se*.

Children were coded as exhibiting the schema on the problem reconstruction measure if they showed evidence of converting at least two problems to typical addition problems (either on the reconstruction task or on the recognition task, as shown in Table 1).

Children were coded as exhibiting the schema on the equal sign definition measure if they showed evidence of thinking that the equal sign means "the sum" or "the total." Children could show this in one of two ways. They could express the idea of adding or totaling in the definition they provided (as shown in Table 1). Or, they could rate the definition "the total" as "very smart."

Children were categorized according to the number of pretest measures (out of three) on which they exhibited the typical addition schema. Thus, children were placed into an overall typical addition schema category of 0, 1, 2, or 3. The number of measures on which the schema was exhibited was considered to be a reflection of schema strength.

Table 1 presents examples of schema-based and non-schema-based responses on each measure. Notice that children's responses are incorrect whether they exhibit the typical addition schema or not. Moreover, there is no reason to believe that the thinking of children without the typical addition schema is "closer to correct" than is the thinking of children with the schema. For example, defining the equal sign as "the answer" is just as incorrect, if not more so, than defining it as "the total." Thus, outside of the present framework, there is no reason to expect learning differences between children who do or do not exhibit the typical addition schema.

Table 1: Example Schema-based (SB) and Non-schema-based (NSB) Responses for the Problem $3 + 4 + 5 = 3 + \underline{\quad}$

	Strategy (Solution Explanation)	Reconstruction	Equal Sign Definition
SB	15 "I added 3 plus 4 plus 5 plus 3."	$3 + 4 + 5 + 3 = \underline{\quad}$	"Add up all the numbers together."
	14 "I added them all up."	$3 + 4 + 5 + 3$	"The total of the problem."
NSB	4 "4 comes after 3 in the pattern."	$3 + 4 + 5 = 3 =$	"Put your answer."
	24 "3 and 4 and 5, times 2 is 24."	$3 + 4 + 5 = + 3 \underline{\quad}$	"It's like where you end the problem."

Results

Manipulation Check

We examined pretest to posttest changes in children's performance on the problem reconstruction and equal sign definition measures as a check on whether our interventions provided children with new ways of thinking about the equivalence problems, as they were designed to do. A 2 (problem reconstruction intervention or no problem reconstruction intervention) \times 2 (equal sign definition intervention or no equal sign definition intervention) ANOVA was performed with pretest to posttest change in number correct on the reconstruction measure (out of 6) as the dependent variable. As expected, the analysis revealed a significant main effect for problem reconstruction intervention, $F(1, 63) = 4.35$. Children who received the problem reconstruction intervention improved their performance on the reconstruction measure from pretest to posttest ($M = +1.78$, $SD = 1.31$) more so than did children who did not receive the intervention ($M = +1.00$, $SD = 1.65$). Neither the main effect for equal sign definition intervention nor the interaction was significant (both F s < 1).

A similar 2 \times 2 ANOVA was performed with pretest to posttest change in difference score on the ratings portion of the equal sign definition measure as the dependent variable. Recall that a positive difference score indicates that definitions such as "the same as" and "equal to" were rated as smarter than definitions such as "the answer" and "the total." As expected, the analysis revealed a significant main effect for equal sign definition intervention, $F(1, 63) = 25.62$. Children who received the equal sign definition intervention improved their difference score from pretest to posttest ($M = +1.94$, $SD = 2.0$) more so than did children who did not receive the equal sign definition intervention ($M = -.12$, $SD = 1.23$). Neither the main effect for reconstruction intervention nor the interaction was significant ($F < 1$ for both).

The preceding analyses indicate that the interventions provided new information about the equivalence problems and that children were, in general, able to take in the presented information in its specific form. The main question at hand is how this new information

affected the way children solved the equivalence problems. The interventions themselves did not predict pretest to posttest changes in problem solving, $\chi^2(3, N = 67) = 3.89$. This is not surprising given that we predicted that children would be differentially affected by an intervention depending on the strength of their typical addition schema.

Effects of Addition Schema

Recall that all children solved the problems incorrectly at pretest. Similarly, only three of the children responded correctly to all six problems on the reconstruction measure at pretest, and none of the children provided an equal sign definition that expressed the concept of equivalence at pretest. It is also important to note that children's pretest schema category (0 to 3) was independent of whether they participated in the control intervention or in one of the experimental interventions, $\chi^2(3, N = 67) = 3.89$. Our main question was whether the strength of the typical addition schema influenced children's tendency to resist changes in the way they solved the equivalence problems after an intervention that provided new ways of thinking about the problems.

Table 2: Number of children in each typical addition schema category who changed or did not change their problem-solving strategy from pretest to posttest.

Number of Pretest Measures Reflecting Addition Schema	Change	No Change
0	5 (100%)	0
1	14 (64%)	8
2	13 (42%)	18
3	1 (11%)	8
$\chi^2(3, N = 67) = 12.88$		

Children were classified as changing their problem-solving strategy if they solved any of the three, posttest problems using a different strategy than they used to solve the pretest problems. Table 2 displays the number

of children who changed or did not change their strategy from pretest to posttest in each of the typical addition schema categories. As shown in the table, children who exhibited the addition schema on all three measures were highly unlikely to change their strategy from pretest to posttest. Again, all children used an incorrect strategy at pretest, so it was the typical addition schema in particular that was associated with change resistance. All of the children who did not exhibit the schema on any of the measures changed their strategy from pretest to posttest. Such a high proportion of change is surprising, given that the intervention lasted only one minute.

Although we were primarily interested in how a strong schema influences change after an intervention, we were also curious about the correctness of children's strategies at posttest. Results were similar when correctness of posttest strategy was used in the analysis in place of pretest to posttest strategy change. Children were classified as having a correct problem-solving strategy if they solved any of the three, posttest problems using a correct strategy. For example, children would be classified as having a correct strategy for the problem $3 + 4 + 5 = 3 + __$ if they put the solution "9" in the blank and said that they added 4 plus 5 to get 9. Of the 9 children who exhibited the schema on all three measures, only 1 (11%) used a correct strategy on the posttest. Of the 31 who exhibited it on two measures, 10 (32%) used a correct strategy on the posttest. Of the 22 who exhibited it on one measure, 8 (36%) used a correct strategy on the posttest. All 5 (100%) who did not exhibit the schema on any of the measures used a correct strategy on the posttest. The analysis revealed a significant relationship between the strength of children's addition schema at pretest and whether or not they used a correct strategy on the posttest, $\chi^2(3, N = 67) = 11.52$.

Discussion

The results of the current study indicate that the strength of the typical addition schema can interfere with children's ability to change their way of solving mathematical equivalence problems after an intervention that provided new ways of thinking about the problems. Moreover, children who did not exhibit the typical addition schema did not merely change their strategy for solving the problems after an intervention, but actually changed to using a correct strategy.

These results complement previous work that has suggested that strong schemata resist change (e.g., Allport, 1954; Bruner, 1957; Luchins, 1932; Schutzwohl, 1998). The present study indicates that individuals who have a strong schema resist changes in their thinking even after an intervention that supplies new ways of thinking. This finding may provide a potential avenue for investigation into individual differences in learning. When a group of students is presented with a particular instruction, why do some

fail to learn or change, while others succeed? Although it is only speculation at this point, it may be the case that individuals who have difficulty learning new ideas are less flexible and more resistant to change because they develop strong, inaccurate schemata more readily than do individuals who are precocious learners.

The present study also extends previous research about schemata by introducing a new way of operationalizing schema strength. Some accounts have defined schema-like structures according to well-practiced action patterns (e.g., Luchins, 1942), while others have emphasized perceptual (e.g., Guion et al., 2000) or conceptual (e.g., Hannigan & Reinitz, 2001) information. In the present study, children exhibited the typical addition schema in their action procedures (i.e., problem-solving strategies), perceptual encodings (i.e., problem reconstructions) and conceptual knowledge (i.e., equal sign definitions). Results provide support for the notion that the strongest, most change-resistant schemata are ones in which all three of the knowledge sources converge on the same idea. Thus, if educators wish to build strong, accurate schemata in their students, they should not focus on building up one aspect of knowledge at the expense of the other two.

The current research has additional implications for educators. Specifically, findings suggest that a strong typical addition schema carries a heavy price and may put children at risk for difficulties in later years when algebraic equations become the focus of mathematics instruction. Thus, educators may want to consider expanding and varying the context in which they present the operation of addition and the equal sign so that children are less likely to form an inaccurate schema from their experience. More generally, results suggest that children's existing knowledge can interfere with the ability to learn new information. Thus, educators should be cautious about what they infer about children's abilities based on proficiency with today's topic.

Acknowledgments

This work was supported by National Science Foundation Child Learning and Development grant #BCS-0096129 to Martha Alibali. We thank members of the Cognitive Development Research Group at the University of Wisconsin for helpful discussions, Jerry Haefel for comments on a previous version of this paper, and Maureen Kaschak for help with data collection. We also thank the students, parents, educators at Frank Allis, Van Hise, Marquette, Sacred Hearts, Edgewood, and Our Redeemer schools. We would especially like to thank Mrs. Burwell's third-grade class at Sacred Hearts school for their generosity and enthusiasm. A preliminary report based on a subset of the data described herein was presented at the October 2001 meeting of the Cognitive Development Society, Virginia Beach, VA.

Abstract

We constructed a virtual psychology laboratory (called VPL) on a computer. VPL simulates the process of pair subjects collaboratively solving Wason's 2-4-6 task, which has been traditionally used in the field of the psychology of discovery science. Participants were required to study collaborative problem solving while repeating experiments and hypothesis revisions using VPL. We conducted three experimental sessions using VPL. As a result, we confirmed, across the sessions, the improvement in various types of participant's performance, such as the organizational construction of experimental design, the degree of correctness of hypotheses the participants formed, and the generality of findings they discovered.

1. Introduction

It is one of the most important objectives in scientific research to understand the behavior of complex systems, such as physical, chemical, and biological systems. For example, psychologists, regarding humans as complex systems, try to identify the factors that determine the behavior of the systems (humans) through psychological experiments. Various types of knowledge are needed to organize psychological experiments. The ability to control experimental factors, CVS (the Control of Variables Strategy), is regarded as one of the most important skills. Klahr et al. have empirically studied the CVS ability of various types of subjects, such as elementary school students, university undergraduates, and graduates majoring in psychology, by analyzing the discovery process for programming grammar to manipulate a toy vehicle called BigTrak (Klahr, 2000). Moreover, they tried to apply the findings on CVS ability obtained in their laboratory studies to a real educational environment (Klahr, 2001).

Schunn and Anderson constructed a simulated psychology laboratory, called SPL, on a computer. Using SPL, they conducted an experiment in which university students and professional psychologists participated, and analyzed their abilities for designing and interpreting experiments (Schunn & Anderson, 1999). In their analysis, they discussed the difference between the general domain-independent and domain-

dependent skills used by each participant for planning psychological experiments.

Additionally they proposed that SPL could be used as a learning environment for tutoring in experimental planning skills (Schunn & Anderson, 2001). However, in SPL, two ad hoc theories were given to the participants; and the participants were required to plan experiments that determined which of those two theories was valid. The process of forming theories (hypotheses) was ignored. Additionally, SPL did not actually simulate the human cognitive process, but simply output subjects' performances, using a previously installed function, as numeral values of the parameters input by the subjects. The process through which the output was obtained was not considered. In the present study, we construct a more realistic and complex experimental environment called VPL (Virtual Psychology Laboratory). Using VPL, we let university undergraduates experience conducting psychological experiments that lasted for several hours.

Schunn and Anderson were mainly interested in how the participants' behavior changed based on their degree of expertise in the research domain concerned. Our interest, on the other hand, is to show changes in the participants' behavior, such as in the formation and verification process of hypotheses including the stage of experimental planning, as a function of their training. We are also interested in the effect of VPL as a simulated psychology laboratory on the training and the improvement of learner's experimental behavior.

2. Experimental environment

2.1 VPL: Virtual Psychology Laboratory

In VPL, two production systems collaboratively solve a traditional discovery task: Wason's 2-4-6 task (Wason, 1960). The mission given to participants was to study factors determining the systems' performance. We can think of the factors determining the performance as, for instance, the degree of difference between the two systems' strategies, the interaction between those strategies and nature of targets, and the capacities of the systems' working memory.

It should be noted that this research theme being used for VPL is a highly realistic subject that has been

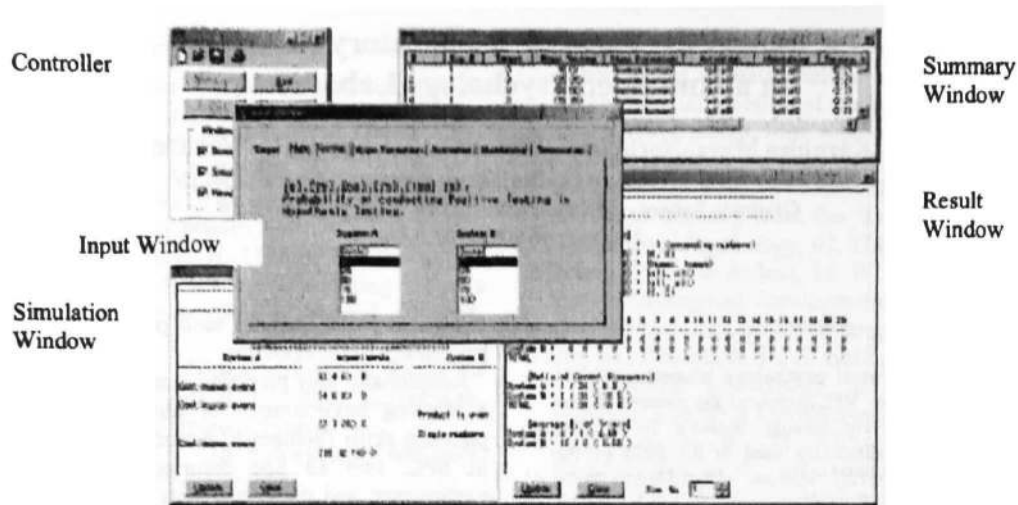

Figure 1: System's interface.

discussed, through recent decades, by psychologists studying human collaborative discovery in laboratory studies (Gorman, 1992; Laughlin, et al., 1997). Moreover, it is also important to note that the psychological validity of this simulator has been tested by our several experiments. The system's performance is determined according to an actual simulation of solving the task. We have already confirmed that the performance of this simulator reflects that of humans well (Miwa, 2001). Figure 1 shows the interface of VPL.

The "Controller" manages the starting and ending of simulations and the appearance of each window. The participants set up experimental factors in the "Input Window". The "Simulation Window" presents a real time process of two production systems solving the Wason's 2-4-6 task. The "Result Window" shows the final result of each simulation. The "Summary Window" summarizes the experimental results obtained by the preceding simulations.

Table 1 shows the experimental factors that the participants can manipulate. Five of the six factors (excluding "Target") are specified in each of the two production systems. In the following experiment, the values of two parameters (# of activated instances and # of maintained hypotheses) were fixed at "all"; the participants could manipulate only the other four parameters. The performance of the simulator is determined by various factors. The fundamental nature of its behavior, such as the existence of interaction between the generality of the targets and the hypothesis-testing strategy (Klayman & Ha, 1987) and a main effect of the working memory capacity (# of activated instances and # of maintained hypotheses), is thoroughly consistent with the findings that several psychologists have reported in real psychological experiments.

2.2 Experiment

Participants: Twenty undergraduate students, not majoring in psychology, participated in the experiment as a part of a university class.

Background knowledge: Prior to the experiment, the participants learned the experimental procedure of Wason's 2-4-6 task, and also the research objectives and motivations of laboratory studies using this kind of simple task. In a preliminary class, the participants read a research paper, which was experimental material prepared by the authors. The paper indicated the experimental result when a single subject solved the task. The result showed that there was interaction between the hypothesis-testing strategy and the nature

Table 1: Factors determining the simulator's

Factors	Levels
Target	[#1] - [#35] Thirty-five kinds of targets used in the experiment. For example, Target #1 is "ascending numbers"; Target #35 is "three different numbers".
Hypothesis testing strategies	[0], [25], [50], [75], [100] The probability of conducting positive tests in generating instance [100] and [0] mean that the simulator always conducts positive tests and negative tests, respectively.
Hypothesis formation strategies	[human], [random], [specific], [general] [human] means that the simulator generates hypotheses as human do. [random]: generating hypotheses randomly. [specific]: generating specific hypotheses prior to general ones. [general]: generating general hypotheses prior to specific ones.
# of activated instances	[all], [6], [5], [4], [3] The number of instances that can be activated at once in the working memory when generating hypotheses.
# of maintained hypotheses	[all], [5], [4], [3], [2] The number of previously rejected hypotheses that can be maintained in the working memory.
Condition for terminating the search	[all], [5], [4], [3], [2] The number of continuous confirmations when the simulator terminates the search. [2] means when a hypothesis is continuously confirmed two times, the simulator recognizes the hypothesis as the final solution, and terminates the search.

of the targets. The participants took part in the experiment after understanding this finding.

Procedure: Three experimental sessions were conducted at intervals of a week. Each session lasted for one hour and a half. At the end of each session, the participants were required to report the findings they had obtained from a series of experiments in the session.

The participants' behavior in each experimental session basically repeated the following procedures. First, the participants entered, in the experimental sheet, (1) the objectives of the experiment they would perform (what are they investigating?), (2) the prediction of the experimental result, and (3) the experimental planning used for controlling experimental factors (which factors are focused on and which levels of each factor are searched?); then they performed the series of experiments planned in the experimental sheet, by manipulating the simulator. After obtaining the experimental result, they entered (4) the interpretation of the experimental result. The participants repeated this series of procedures until the end of the session.

Pre- and Post- tests: Before and after the three experimental sessions, pre- and post- tests were conducted to measure the subjects' fundamental ability to control experimental factors.

3. Experimental results

3.1 Chunking behavior

We define a set of organized experiments as a chunk. Thus, we think of a more sophisticated construction of experimental planning as a process of constructing higher chunks (Miwa, 2000).

The participants conducted their experiments by searching the experimental space as depicted in Figure 2. As mentioned before, two factors, # of activated instances and # of maintained hypotheses, were fixed at the value "all". The participants manipulated the simulator and obtained experimental results after filling

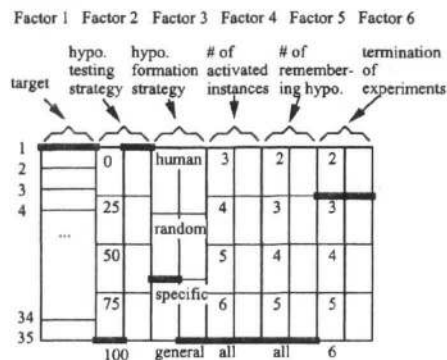

Figure 2: The experimental space searched by Ss.

in the experimental sheet. A set of experiments planned in a piece of the experimental sheet is regarded as a unit of experiments. Almost all experimental planning (about 96%) entered in a piece of the experimental sheet was constructed based on the factorial experiment design. So, for example, when p levels and q levels in each of two factors were searched, a total of $p \times q$ experiments was completely performed according to the experimental planning. We excluded, from the following analysis, units of experiments (4%) which violated this factorial experiment design.

We regard this set of experiments planned in a piece of the experimental sheet as the most basic chunk. We call this basic chunk a "Unit". The participants combine multiple Units to construct a higher chunk. We propose the following two types of chunking, Type A and Type B, as methods for constructing a higher chunk.

See Figure 3 in which a Unit is constructed by the set of experiments where some levels of Factor n and Factor m are searched. The first type of chunking is Type A (Figure 3(a)) where the searcher shifts a searching level of Factor k one by one, while maintaining the search of Factor n and Factor m . The set of these experiments can be grouped as a chunk of experiments in which three factors, Factor n , Factor m , and Factor k , are simultaneously controlled. The important point is that factors other than the controlled

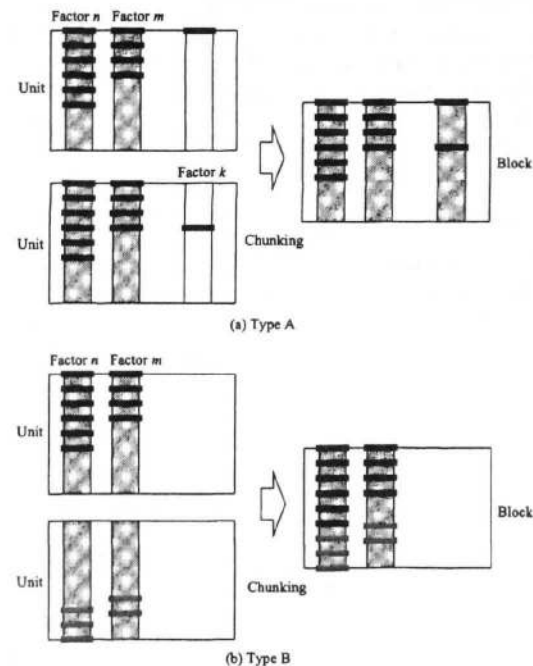

Figure 3: Two types of chunking behavior.

three factors are fixed at an identical level.

The second type of chunking, Type B (Figure 3(b)), occurs when it is impossible that all levels involved in the focused factors, such as Factor *n* and Factor *m*, can be searched at the same time; the search is divided into multiple Units. In this case, the set of multiple Units can also be seen as a chunk. The point is that factors other than Factor *m* and *n* are fixed.

By using these two types of chunking, bigger chunks can be constructed from multiple basic Units. We call these higher chunks "Blocks". Here we define the compression ratio of chunking based on the number of individual experiments constructing a single Block. For example, in Figure 3 (a), one Block is constructed from 48 experiments [= 6 (Factor *n*) x 4 (Factor *m*) x 2 (Factor *k*)]; so the compression ratio of chunking is 0.021 (= 1/48). On the other hand, in Figure 3(b), as 30 experiments (= 6 x 4 + 3 x 2) construct a Block, the compression ratio of chunking is 0.033 (= 1/30). The smaller ratio of chunking means that the participants are able to construct a bigger chunk in their experimental behavior. Consequently, the compression ratio of chunking reflects the degree of participants' organizational experimental behavior.

Figure 4 shows, for each of the three experimental sessions, the average compression ratio of chunking of the 16 out of 20 participants, who participated in all of the three experimental sessions. (Similarly analyses of these 16 subjects' results are shown in sections 3.2, 3.3, and 3.4.) As the experimental sessions proceeded, the compression ratio of chunking decreased. As a result of ANOVA, a main effect of the experimental sessions was significance ($p < .01$). This result confirms that the participants learned to construct bigger chunks, i.e., exhibited more organizational behavior, through repeating experimental activities.

3.2 Controlled factors

We can also confirm the process of constructing bigger chunks by analyzing the transition of the number of controlled factors by the participants across the three

Figure 4: Transition of the ratio of chunking.

experimental sessions. Figure 5 shows the average ratios of the number of Blocks, in which one, two, and three or more factors were controlled, to the number of all Blocks. As the experimental sessions proceeded, the ratio of Blocks manipulating more than three factors increased, whereas the ratio of Blocks manipulating one factor decreased. As a result of ANOVA, there was interaction between the experimental sessions and the number of controlled factors ($p < .05$). A simple main effect of the experimental sessions at each of the two single levels, one and more than three, in the number of controlled factors was significance ($p < .05$ and $p < .01$ respectively). The result above shows that the participants learned, during the progress of the experimental sessions, to conduct experiments in which a greater number of various factors were manipulated.

3.3 Hypotheses

We also focused on the hypotheses formed by the participants.

The participants entered their prediction of the experimental results in the experimental sheet before executing a series of experiments. At that time, they also estimated the degree of confidence in the prediction on a 1 to 5 scale. Additionally, after executing the experiments with the simulator, they entered their interpretation of the experimental results. At that time, they also estimated the degree of correctness of their prediction on a 1 to 5 scale.

Figure 6 shows the average degree of confidence estimated before executing experiments and the average degree of correctness estimated after the experiments. The figure indicates that the degree of correctness was improved from the first to third sessions while the degree of confidence was almost constant. As a result of ANOVA, there was interaction between the experimental sessions and the two kinds of participants' estimation (the degree of confidence and correctness) ($p < 0.01$). A simple main effect of the experimental

Figure 5: Transition of the number of controlled factors.

Figure 6: Transition of the degree of confidence/correctness of hypotheses.

sessions at the degree of correctness revealed significance ($p < 0.05$) whereas an effect at the degree of confidence did not.

The degree of correctness reflects the objective validity of the participants' hypotheses whereas the degree of confidence reflects the participants' subjective estimation of the probability of their hypotheses. The invariant of the degree of confidence implies that the change in the complexity of the participants' hypotheses was not so marked between the former and latter parts of the experimental sessions. On the other hand, the improvement in the degree of correctness confirms that the participants learned to form more accurate hypotheses during the progress of their experiments even though the complexity of the hypotheses was almost constant.

3.4 Findings

Next we move to an analysis of the findings that the participants discovered. As mentioned before, the participants were required to report their findings at the end of each experimental session.

We categorize the findings from the viewpoint of their generality. We define participants' general conclusions mentioning the relation between an experimental factor (or factors) and the system's performance as general findings. For example, the conclusion, "positive testing is effective in finding the specific targets whereas negative testing is effective in finding the general targets", is an example of a general finding because the participants mention the relation between the two factors, the nature of targets and the hypothesis-testing strategies, and the system's performance. On the other hand, we define restricted conclusions mentioning a factor (or factors) determining the system's performance only in a specific situation as specific findings. For example, the conclusion, "in terms of target #27, negative testing is

Figure 7: Transition of the number of specific/general findings.

effective", is an example of a specific finding because this conclusion mentions a restricted finding for a specific case: target #27.

Figure 7 shows the average number of specific and general different findings in the first and third experimental sessions. The figure shows that the number of general findings increased across the sessions while the number of specific findings decreased. As a result of ANOVA, there was interaction between the experimental sessions and the nature of findings (specific and general) ($p < 0.01$). Simple main effects of the experimental sessions at both levels of specific and general in the nature of findings revealed significance ($p < .01$ and $p < .05$ respectively). This confirms that the participants gradually came to discover general findings during the progress of the experimental sessions.

3.5 Improvement from Pre test to Post test

Lastly, we discuss whether the participants learned general procedural knowledge on experimental planning by analyzing the pre- and post- tests that were carried out before and after all of the experimental sessions.

In the pretest, the participants were required to plan an experiment that identified the factors (temperature and/or humidity) responsible for the growth of bacteria. In the posttest, an isomorph of the problem in the pretest was used where the participants were required to identify the factors causing the growth of plankton. The participants' solutions in each test were categorized into two types: (1) for identifying the factors determining the growth of bacteria or plankton, first varying one factor while fixing the other factor then manipulating that other factor (that is, first varying humidity while fixing temperature then varying temperature while fixing humidity); and (2) simultaneously controlling both two factors. We call

Figure 8: The comparison of experimental planning in the pretest and the posttest.

the former planning a "combined one factor experiment", and the latter a "two factors experiment". The latter planning is more sophisticated because it can detect interaction between the two factors, but the former cannot. Figure 8 shows the comparison of the solutions of 19 participants in the pretest and in the posttest. One of the 20 participants was excluded from the analysis because the subject indicated a confusing answer. Fisher's exact analysis supported a tendency in the increase of the two factors experiment in the posttest compared to in the pretest ($p < .1$).

The above result confirms that some of the participants successfully acquired general procedural knowledge on conducting appropriate experimental planning through repeatedly performing experiments using VPL.

4. Discussions and conclusions

In this experiment, the participants were not given any instruction from a tutor. The participants experienced the three experimental sessions receiving the feedback from the simulator while repeatedly performing their experiments by themselves without any instruction from others. However, the various types of participants' performance, such as organizational designing of experiments, the degree of correctness of formed hypotheses, and the generality of findings, were remarkably improved. This implies that this kind of exercise using a simulated research environment, such as VPL, could be effective for providing tutoring in psychological activities to students who begin to learn experimental psychology.

We understand that it was still not clear that these improvements were brought about by the learning of general experimental skills such as CVS or simply by the increase of information on the problem space searched during the progress of the experiments. However, we believe that the improvement of the scores from the pretest to the posttest confirms that some of the participants had learned something related to general skills on experimental planning because the contents of those tests were independent from those dealt with in the exercise using VPL. At any rate, the

experimental results support the possibility of achieving "learning by doing" without instructions through this sort of relatively short-term exercise by using a VPL-like learning environment (Anzai, 1979).

In our future work, we will examine the usage of VPL as an experimental microworld. We could clarify, for instance, the difference between Novices' and Experts' experimental processes and the effects of background knowledge on the processes. We will also further discuss on the possibility of using VPL as a tutoring system. For example, it might be possible to activate the participants' learning process by giving informative feedback to learners based on the idea of constructing higher chunks.

Learning to Solve Complex Propositions: Does knowledge of truth-values bootstrap modal operators?

Abstract

Evaluating complex propositions requires evaluating truth-values and assigning modal operators. Previous research suggested that evaluating truth-values may be the key to assigning modal operators. This study placed 111 third and fifth grade children in one of three training conditions: no training, training truth-value assignment, and training truth-value and modal operator assignment. The results indicate that truth-value assignment training is sufficient to significantly improve children's evaluations of complex propositions.

Reasoning with complex propositions (statements using AND, OR, NOT, IF) forms the basis of much higher-order thinking. There are three reasoning classes associated with processing propositions: evaluating a proposition as true or false (truth-values), evaluating whether a conclusion follows from the premises (validity), and judgments about possibility and necessity (modal operators). While much research has focused on judgments about validity (for a recent review see Markovits & Barrouillet, 2002), we will focus on a less-researched area: evaluating truth-values and assigning modal operators.

The assignment of truth-values entails determining the truth or falsity of a statement (Johnson-Laird, 1983). The complexity of assigning truth-values depends on the number of elements being evaluated (i.e., how many items need to be evaluated) and the number of states under evaluation (the number of combinations and their associated truth-values). To better illustrate this point we will provide examples of two representative tasks. The first is sentence verification. In a sentence verification task, subjects typically are given a simple proposition (e.g., the star is white) to evaluate either with their existing knowledge or with some reference materials (e.g., picture of a white star). There are two possible values for each proposition: true or false. Because there is only one element under consideration, the evaluation is based on semantic properties (Roberts, Wood, & Gilmore 1994). The second type of task, evaluating complex propositions such as conjunctions and disjunctions, is more complicated than sentence verification because it requires the evaluation of two elements and four possible states. For example, when evaluating a conjunction (e.g., the star is white and the circle is blue), each single proposition

has its own truth-value (white star; blue circle). Additionally, the statement as a whole is only true if both single propositions are true, thus there is only one of the four possible resulting combinations that results in an assignment of "true" for the entire statement.

Assigning modal operators is determining when a statement is possible or necessary (Johnson-Laird, 1983). Like the assignment of truth-values, the assignment of modal operators differs in complexity depending on the nature of the task. Modal operators can be assigned on statements such as "A brother is a boy" in which by definition the statement is necessarily true (Miller, Custer, & Nassau, 2000). In this task the assignment is based on purely semantic factors. A more difficult task is assigning modal operators for complex propositions such as contradictions and tautologies. To determine that a tautology is always true (possible) and that a contradiction is always false (impossible) requires evaluating the semantics and syntax of the statement. That is, one must consider the truth-value of the connective and whether the semantic elements match any of the possible truth-values. Thus, a contradiction will always be false because one of the two propositions will always be false and an AND statement requires both elements to be true for the entire statement to be true.

Development of Truth-values and Modal Operators

Very little attention has been given to how children coordinate assigning truth-values and assigning modal operators. That is, are these processes related and if so, how? Perhaps gains on one phase do not correspond to gains on the other, thus we will call this possibility the *separate phase hypothesis*. Much previous research on either process has focused on a single process without examining the other typically reporting performance in one without respect to changes in the other (Ruffman, 1998; Braine & Romain, 1981; Osherson & Markman, 1976; Paris, 1974). Thus, perhaps the two are not related.

The only theoretical position that has examined both processes, mental logic, states that the two processes are part of a single inferential schema that is acquired with language (Braine & O'Brien, 1997). Once activated, these schemas fire a series of inferential rules that produce a

correct conclusion for all types of inferences (truth-values and modal operators). Thus this position suggests that children should either err on assigning truth-values or modal operators or produce correct evaluations for both, but there should be no inconsistency. We will call this approach the *compiled phase hypothesis*. Previous research demonstrates differences in young children's ability to assign truth-values and modal operators (Morris & Sloutsky, 2002; Miller, Custer, & Nassau, 2000; Braine & Romain, 1981; Osherson & Markman, 1976), however, most of this research did not look at the consistency of responses within individual children. Two studies that examined within-participant consistency (Morris & Sloutsky, 2002; Morris & Klahr, in review) found large differences in children's performance specifically, that children produced correct responses on assigning truth-values before modal operators. These differences may suggest that such coordination in these types of inferences may occur late in development (see Morris & Sloutsky, 2002, for a discussion).

It is also possible that the two types of inferences are related and that knowledge about one is related to the development of the other. We will call this the *dependent phase hypothesis*. Morris & Sloutsky (2002) and Morris and Klahr (in review) examined children's assignment of truth-values and modal operators and observed that many children erred on one while giving correct responses on the other, providing evidence against the compiled phase hypothesis. Further, in each case, children who correctly assigned modal operators also assigned correct truth-values while the converse was not true suggesting that the ability to assign correct truth-values preceded the ability to assign correct modal operators. The *dependent phase hypothesis* suggests that children must first learn to assign correct truth-values before they can assign modal operators because the mappings that allow truth-value provide sufficient information to infer modal operators.

The present study was designed to compare the three approaches and to test the dependent-phase hypotheses. A training study was conducted in which children were given instruction on assigning truth-values and modal operators. Children were randomly assigned to one of three conditions. The first instructional condition ("mapping") provided explicit instruction on evidence evaluation only. The second instructional condition ("necessity") gave children explicit instruction on evidence evaluation and evidence requests. The third condition ("control") gave children no instruction.

Our first prediction is that mere exposure to logical statements is insufficient to improve performance on any processing phase. If all conditions show equal improvement on the post-test, then this supports the compiled phase hypothesis because learning was not required, only familiarity with the type of problem. The second prediction is that training is necessary for improvements in performance. If the mapping and necessity conditions show significant improvement from pre- to post-test and children's performance in these conditions are significantly better than the performance of children in the control

condition, this provides evidence against the compiled phase hypothesis (because training was required to improve performance) and supports the separate and related phases hypotheses. The third prediction is that improvement is specific to the phases on which training has been given. If children in the mapping and necessity condition are not be significantly different in their post-test performance levels then this supports the dependent phase hypothesis, however, if the mapping and necessity conditions are different on the post-test, then this supports the separate phase hypothesis.

Method

Participants

The participants were 111 children: 60 third (mean age 8,8; 29 boys, 31 girls) and 51 fifth (mean age 10,8; 25 boys, 26 girls) graders enrolled in two public or two private schools located in Pittsburgh, Pennsylvania. Participants were chosen on the basis of returning a parental consent form. Third and fifth grade children were selected because cross-sectional studies (e.g., Morris & Sloutsky, 2002) have demonstrated significant improvements in logical reasoning between these ages. Children in each grade were randomly assigned to one of the three conditions.

Design

We used a 3 (condition) x 2 (grade) x 4 (session) design with session as within-participants measure. The three conditions (control, mapping, necessity) differed in the amount of explicit instruction on how to evaluate different types of logical statements. The control group was given a series of 12 problems formally identical to those in the pretest in both training sessions without any instruction. Children in the mapping condition were given explicit instruction about rules used to evaluate evidence in logical statements. Children in the necessity condition were given the same evaluation rules as those in the mapping condition and were given explicit instruction about when evidence was necessary and unnecessary.

Each child participated in four sessions: a pre-test, training 1, training 2, and a post-test. In the pre-test, children were asked to evaluate the truth-status of a series of 16 statements. In the second and third sessions children were given one of the three training conditions. In the fourth session each child was given a post-test formally identical to the pre-test.

Procedure

The procedure was divided into four sessions over four days: (1) Day 1- Pre-test, (2) Day 2- Training 1, (3) Day 3- Training 2, (4) Day 4- Post-test. Each session was separated by approximately one week ($M = 8.2$ days). Each child was interviewed individually in a quiet location in his or her school. The interviewer recorded each child's responses for all four sessions.

Session 1- Pre-test

All instructions for the experimental segment were read to each participant and repeated if requested. The pre-test consisted of 4 warm-up statements and 16 actual statements. Two cards were placed in front of each child: a statement card (face up) and an evidence card (face down). The order of presentation of statement and evidence pairs was counterbalanced across participants. Each child was presented a total of 16 statements corresponding to 4 of each of the following types: conjunctions, disjunctions, tautologies, and contradictions. The child then read the statement card aloud. After the child read the statement, Question phase 1 (*a priori* evaluation) was then asked ("Is the sentence true, not true, or can't you tell?"). After the answer was recorded, Question phase 2 was asked (evidence request: "Do you need to see the picture to find out?"). If evidence was requested, the evidence card was turned over (all were pictures) and placed in front of the participant. Question phase 3 was then asked (evidence evaluation) in which the child was asked to evaluate the initial statement using the evidence requested ("Now that you have seen the picture, was the sentence true, not true, or can't you tell?"; Asked only if evidence was requested). The task took approximately 15 minutes.

Session 2- Training 1

Control Condition. The procedure used in the control condition was identical to the procedure used in the pre-test. Children in the control condition were given a set of 12 statements structurally identical to those in the pre-test but with altered content. As in the pre-test children were asked up to three questions for each statement corresponding to the three processing phases. Children were given no feedback or instructions after their responses. This procedure lasted 10 minutes.

Training Warm-up Segment. Note the training warm-up was used only with the mapping and necessity conditions. The training warm-up segment was a brief session in which children were given basic rules for evaluating evidence with the connectives AND or OR. The training consisted of three parts: (1) explanation of sentence parts, (2) explanation of evaluation rules, and (3) rule use/feedback. Children were first given an explanation of the "parts" of each sentence in the task. Each sentence was divided into two parts (clauses separated by the connective) and an "important word" (the logical connective). Children were told that the important word indicated which rule was used to evaluate each type of statement.

Children were then asked to demonstrate the parts and important words on a new sentence with feedback provided for errors. Next, children were given brief instruction on how to evaluate evidence with each type of important word. Children were given simple rules for each connective. Children were told that the evidence had to match both parts for an AND sentence to be true, otherwise it is false. Children were told that evidence had to match only one part of the statement for an OR to be true otherwise the

statement is false. The decision to explain an OR as an exclusive OR was made to make a clean conceptual distinction between OR and AND.

Once the rules for important words were explained, children were given a statement and a series of evidence cards, presented one at a time, and asked to identify the parts and important word then to evaluate the statement as a whole. In total, two statements (1 OR, 1 AND) and four evidence cards (1 true, 1 false for each statement type) were given over the training warm-up. Feedback was provided for incorrect responses giving the correct answer and re-explaining the evaluation rule. This procedure took 5 minutes. The warm-up was only given before Training 1.

Mapping Condition. The mapping condition provided explicit instruction about evaluating evidence with statements. Each child was given four statements (one of each type) and three different pieces of evidence for each statement. The mapping condition provided instruction for each statement in three stages over which the scaffolding provided by the interviewer was gradually reduced: (1) explicit instruction, interviewer-led solution, (2) probe questions, scaffolded solution and (3) probe questions, child-led solution.

In the first stage of the instruction, the interviewer placed a statement card on the table and asked the child to evaluate the statement as true, not true, or can't tell. The interviewer then placed the first evidence card on the table and asked the child to evaluate the statement based on the evidence card. The interviewer then provided explicit instruction about the parts and important words of each statement and the correct conclusion regardless of the child's response. The second evidence card was then placed on the table beside the first evidence card. The interviewer asked the child to repeat the rule for the important word, match evidence to each part of the sentence, and then to evaluate the sentence as a whole. If any evaluation was incorrect, children were given immediate feedback. The third evidence card was placed on the table beside the first two cards. The interviewer then asked the child evaluate each part of the sentence and evaluate the sentence as a whole. Feedback was provided only if the child answered incorrectly. This procedure was repeated for each statement type and took approximately 10 minutes per child.

Necessity Condition. The procedure in the necessity condition was identical to the mapping condition with the addition of two probe segments after evaluating the second and third evidence cards. After the second evidence card, the two evidence cards (and the truth-values associated with them) were reviewed to determine if their contents changed the truth-values of the statement as a whole. After the third evidence card, all cards were reviewed. The child was then asked whether the evidence changed the statement's truth-value. If the evidence was necessary, then the child was told that it was necessary to first see evidence before evaluating "this type" of statement. If evidence was unnecessary, then

the child was told that no evidence would change the truth-value of "this type" of statement because, for example, the two clauses in a contradiction can never match the same evidence (in this case the same picture).

Session 3: Training 2

The training 2 was identical to that used in Training 1.

Session 4: Post-test

The post-test procedure was identical to the pre-test.

Materials

Pre- and Post-Test Materials. Pre- and post-test materials were logically identical but had slightly different content. Each session required the evaluation of four statement types: tautology, contradiction, disjunction, and conjunction. Each child saw four instances of each statement type. The materials consisted of 16 unlined 3 x 9" cards with one statement and 16 3 x 5" cards with a corresponding piece of evidence. An additional six cards (3 statement, 3 evidence) were used as materials for the warm-up items.

Control Condition. Two sets of materials (one for each training session) were created for the control condition. Each set contained 12 statements (3 of each type) printed on 3 x 9" cards and 12 3 x 5" evidence cards. Each set also included three statement cards and three evidence cards for the warm-up segment.

Training Warm-up Condition. The training warm-up (for mapping and necessity conditions only) included two statement cards used to demonstrate the parts of the sentence, plus two statement cards and four evidence cards for articulating the AND and OR rules.

Mapping and Necessity Conditions. The mapping condition required two sets of materials, one for each training session. Each set of materials included four statement cards (one of each statement type) and twelve evidence cards, three evidence cards corresponding to each statement card.

Results

The results will be presented in two sections: (1) aggregated analyses of the effects of training across each processing phase separately and (2) individual strategy analyses comparing changes in the consistency of response patterns across processing phases. The first set of analyses will separately examines training effects on a priori evaluations, evidence requests, and evidence evaluations. The second analysis examines changes in inter-phase consistency before and after training.

Aggregated analyses

Question Phase 1: A Priori Evaluations (AP). For all a priori evaluation phases, possible responses were "true," "not true," or "can't tell." Correct responses were coded as follows: contradictions- not true; tautologies-true; conjunctions and disjunctions-can't tell. Correct responses were scored as 1 while incorrect responses were coded as 0.

To determine the effectiveness of training on the number of correct a priori evaluations, a 3 (condition) x 2 (age) x 2 (pre-test vs. post-test) ANOVA was performed with session as a within-subjects variable. The analysis reveals a main effect for condition, $F(2, 110) = 6.1, p < .003$, and age $F(1, 110) = 8.9, p < .003$ and no interaction between condition and age $F(2, 110) = .42, p > .65$. Children in the mapping and necessity conditions gave significantly more correct responses in the post-test than in the pre-test. The performance of children in the control condition did not differ significantly from pre-to post-test. Fifth graders gave significantly more correct requests in the post-test than third graders.

Question Phase 2: Evidence Requests (ER). For the evidence request phase, possible responses were "yes" or "no." Correct responses were coded as follows: contradictions-and tautologies-No; conjunctions and disjunctions-Yes. Correct responses were scored as 1 while incorrect responses were coded as 0.

To determine the effectiveness of training on the number of correct evidence requests, a 3 (condition) x 2 (age) x 2 (pre-test vs. post-test) ANOVA was performed with session as a within-subjects variable. The analysis reveals a main effect for condition, $F(2, 110) = 3.9, p < .01$, and age $F(1, 110) = 10.6, p < .001$ and no interaction between condition and age $F(2, 110) = .42, p > .65$. Children in the mapping and necessity conditions gave significantly more correct responses in the post-test than in the pre-test. The performance of children in the control condition did not differ significantly from pre-to post-test. Fifth graders gave significantly more correct requests in the post-test than third graders.

Question Phase 3: Evidence Evaluations (EE). For the evidence evaluation phase, possible responses were "true," "not true," or "can't tell." Correct responses were coded as follows: contradictions-not true; tautologies-true; conjunctions (2 true, 2 false) and disjunctions (2 true, 2 false). Correct responses were scored as 1 and incorrect responses were coded as 0.

To determine the effectiveness of training on the number of correct evidence evaluations, a 3 (condition) x 2 (age) x 2 (pre-test vs. post-test) ANOVA was performed with session as a within-subjects variable. The analysis reveals a main effect for condition, $F(2, 110) = 20.8, p < .001$, and age $F(1, 110) = 9.2, p < .003$ and no interaction between condition and age $F(2, 110) = .25, p > .77$. Children in the mapping and necessity conditions gave significantly more correct responses in the post-test than in the pre-test while children

in the control condition did not differ significantly from pre- to post-test. As in previous conditions, fifth graders gave significantly more correct requests in the post-test than third graders.

The aggregated analysis demonstrated that experience with statements was not sufficient to improve performance, at least not in the limited exposure provided during the training period. Training effectively improved performance for children in the mapping and necessity conditions. The next series of analyses will examine the structure of change.

Individual Analysis

The individual analysis examined the consistency of a child's correct response patterns within each processing phase and across all processing phases. For example, although the aggregated data demonstrates that fifth graders generally outperformed third graders, these data do not indicate the extent to which an individual fifth grader produced correct answers for the evidence request phase or for all question phases. We considered a pattern in which 75% of responses were correct as *consistently correct*. A pattern below 75% was considered inconsistent. Tables 1 and 2 display the number of children coded as consistently producing correct responses for each processing phase in the pre- and post-tests.

Table 1- Percentage of Third Grade Children Giving Consistent, Correct Responses Within Each Processing Phase by Condition

Condition	AP	ER	EE
Control	0 (10)	0 (19)	19 (19)
Mapping	5 (30)	8 (40)	5 (85)
Necessity	5 (37)	5 (63)	11 (79)

Note. Posttest scores are presented in parentheses.

Table 2- Percentage of Fifth Grade Children Giving Consistent, Correct Responses Within Each Processing Phase by Condition

Condition	AP	ER	EE
Control	10 (14)	19 (29)	14 (10)
Mapping	15 (59)	10 (60)	25 (80)
Necessity	26 (62)	37 (79)	26 (95)

Note. Posttest scores are presented in parentheses.

There was a significant difference between the number of consistent, correct responses in pretests and in the post-tests for third and fifth graders. Third graders produced significantly more consistent evidence evaluations χ^2 (2, 40.8, $p < .001$) in the post-test than the pre-test. Fifth graders produced significantly more evidence requests χ^2 (2, 10.5, $p < .003$) and significantly more consistent evidence evaluations χ^2 (2, 14.5, $p < .001$) in the post-test than the pre-test.

These data were used to code the child's overall response pattern (i.e., consistency measure on each of the three

processing phases) as either consistently correct (consistent, correct responses on all phases) or mixed (inconsistent on one or more phases). The results are displayed in Table 3. Children in both training conditions produced significantly more consistent correct responses than children in the control condition, third graders χ^2 (2, 4.2, $p < .03$), fifth graders χ^2 (2, 15.1, $p < .001$).

Table 3- Percentage of Children Giving Consistent Correct Responses by Grade and Condition

Condition	3 rd		5 th	
	Pre	Post	Pre	Post
Control	0	9.5	13	13
Mapping	0	20	0	59
Necessity	0	37	11	61

Discussion

The results support the dependent phase hypothesis in which changes in performance are due to gains on knowledge of assigning truth-values, which then lead to improvements in assigning modal operators. We tested three predictions with a training study in which children were given varying levels of instruction. These data indicate that (1) contra the compiled phase hypothesis, a small amount of experience with logical statements is not effective for improving performance. Exposure to the control condition was not related to increases in performance. Training was related to significant increases in performance. Specifically, (2) both training conditions were effective in improving performance but (3) training on assigning truth-values was sufficient to produce consistent, correct responses at levels roughly equal to those of the necessity condition (in which both truth-values and modal operators were trained).

Morris and Klahr (in review) examined the order in which children make consistent correct responses on each processing phase. In all cases, correct evidence evaluation always preceded correct evidence requests and *a priori* evaluations. The authors suggested that correctly evaluating evidence provided sufficient knowledge from which children could make further inferences about problem classes.

The results can be explained by extending mental models theory. In Mental Models theory (Johnson-Laird, 1983), for each problem, models are created and searched for possible solutions. Thus, to derive a valid conclusion, a set of tokens is created and searched for possible and impossible solution states. This constitutes a solution for a single instance. As currently formulated, Mental Models makes no provisions for within-subject change in processing due to learning (e.g., a child's performance on trial 100 should be different than their performance on trial 1). The *dependent phase hypothesis* suggests that this type of change should be demonstrated by improvements on each phase and in the structure of change between processing phases. As currently formulated, mental models suggests that developmental

change is a function of increases in working memory. Although this is likely important, such a factor would not explain improvement derived from experience.

We suggest two possible mechanisms that may facilitate changes in performance: *discrimination* and *compilation*. After seeing a sufficient number of instances, a reasoner should form expectations about a class of similar types (e.g., determinate statements). In this way, a reasoner does not approach each instance as a new problem type. Rather, increased reasoning efficiency results from (1) eliminating redundant or unnecessary steps (Crowley, Shrager, & Siegler, 1997) and (2) making additional inferences about the class of similar problem types (Eisenstadt & Simon, 1997; Morris & Klahr, in review). For example, when reasoning about two propositional classes: indeterminate and determinate formal types, children initially confuse the two, treating both as indeterminate (Fay & Klahr, 1996; Morris & Sloutsky, 2002). By sixth grade, children begin to distinguish the two forms, but often fail to correctly determine when evidence is necessary and when unnecessary (Morris & Sloutsky, 2002).

On first exposure to a formal type, a reasoner may make errors at all phases. In evaluating a contradiction, for example, a reasoner may assert that they cannot assign a truth-value to the statement *a priori*, may request evidence and then fail to evaluate this evidence correctly. Once evidence is correctly evaluated and after several correct conclusions have been drawn, our hypothetical reasoner may then be able to infer that no evidence will change the truth-value of this particular statement. Once this inference is drawn, the reasoner may then also assert that the statement is false *a priori*. The processes described may illustrate (1) compilation, or eliminating a redundant processing step (evidence request), and (2) discrimination, or creating a new conceptual category for "statements that do not require evidence." Once this inference is made about one statement, the reasoner may generalize this to other propositions of this type: a statement of the form (A & ~A) is false.

Logical Strategy

Bradley J. Morris (bjmorris@pitt.edu)

Abstract

We propose a conceptual framework for explaining logical reasoning in terms of competing strategies. Contrary to previous approaches in which a single theory is suggested to explain all logical reasoning, this framework suggests that the core elements of existing theories constitute strategies, each of which have unique processing demands. A strategy is more likely to be used when its processing demands match a problem's task demands. The framework specifies how each strategy may be distinguished theoretically and empirically.

Overview

The study of logical reasoning has typically proceeded as follows: researchers (1) discover a response pattern that is either unexplained or provides evidence against an established theory, (2) create a model that explains this response pattern, then (3) expand this model to include a larger range of reasoning situations. For example, researchers typically investigate a specific type of reasoning (e.g., deduction) using a particular variant on an experimental task (e.g., the Wason selection task). The experiments uncover a specific reasoning pattern, for example, that people tend to match terms between the premises and conclusions rather than derive valid conclusions (Evans, 1972). Once a reasonable explanation is provided for this response pattern, researchers typically attempt to expand this explanation to encompass related phenomena, such as, the role of 'bias' in other reasoning situations such as weather forecasting (Evans, 1989). Eventually, this explanation may be used to explain all performance on an entire class of reasoning phenomena (e.g. deduction) regardless of task, experience, or age. We term this the *unified approach*.

Unified approaches have traditionally suggested that logical reasoning is either rule-based (application of transformation rules that draw valid conclusions once fired; Rips, 1994) or model-based (creating and searching veridical representations of premises and possible conclusions; Johnson-Laird, 1999). It seems possible, however, given the range of problem types, task demands, experience, and cognitive resources of the reasoner, that there may be more than one approach to solving a class of reasoning phenomena.

Logical reasoning tasks are quite varied, ranging from simple tasks such as statement evaluation (e.g., "Is my cat black?") to complex tasks such as predicate syllogisms (e.g., Some A are not B, Some B are C, Some C are not D, Are

some D A?). There is no evidence that logical reasoning occupies a particular region of the brain (cite), that it is a coherent process distinct from the rest of cognition (Johnson-Laird, 1999), or that it involves the same cognitive processes across different tasks. Moreover, cognitive psychology has identified a variety of general cognitive processes that are used to solve a wide variety of tasks (e.g., analogy, retrieval, guessing). Thus, it should not be controversial to suggest a multiple strategy approach- that several, general processes might be used to solve logical reasoning problems in at least some situations, even if there are special logical reasoning processes.

We propose an alternative to the *unified approach* in which a series of simple strategies may be used rather than a single complex theory. Thus, we propose a new framework for explaining logical reasoning performance by incorporating simplified versions of existing approaches as possible strategies for solving logic problems. We list a variety of alternatives that seem highly likely to be used in at least some logical reasoning situations. It is not crucial to the argument here that all strategies are actually used. We will propose conditions under which various strategies may be used, thus proposing a framework through which strategies can be distinguished theoretically and empirically.

The multiple strategy approach has been suggested in the domains of judgment and decision-making (see Bettman, Johnson, Luce, & Payne, 1993, and Todd & Gigeranzer, 1999). Like the logical strategy model, these approaches suggest competition between various strategies in which selection is accomplished, in part, from an evaluation of effort-accuracy tradeoffs. However, the logical strategy model differs from these approaches in their function and goals: (a) the function of the LSM is the creation and evaluation of knowledge (inference) rather than selection and evaluation of knowledge for decision making (judgment), and (b) the goal of LSM is to establish (either through production or evaluation) valid inferences while the goal of other approaches is to return the most adaptive decision (Todd & Gigeranzer, 1999).

The Strategy Approach to Logical Reasoning

What does it mean to think in terms of strategies? A glance at the existing literature suggests that unified approaches have difficulty accounting for differences in performance between individuals and across tasks (for a review see Rips, 1994; Johnson-Laird, 1999). We suggest that differences in performance across individuals and

situations are due to the selection of a strategy and that strategy selection is a function of the history of success with each strategy and the match between processing demands of the strategy and the task demands of the problem. We will describe this match between the processing demands and history of success of the strategy and the situation/task demands as the *situational niche*.

As stated earlier, unified approaches have suggested that a single theory can account for the range of human performance. We suggest that the strategy selection approach may explain the same phenomena by proposing a series of specified approaches, each relegated to explaining a subset of the total range of human deductive performance.

What do we gain from this approach? The strategy approach allows established explanations to be incorporated into a single model in which all are possible explanations of behavior differing only in the extent to which the particular strategy has been used in similar situations and matches the task demands. The match between a particular strategy and its situational niche may not be rational, but may help explain individual and situational differences between theories. For example, it is well established that familiar content tends to improve performance on the Wason selection task (Wason & Johnson-Laird, 1972). Hundreds of experiments have investigated this phenomenon and have led to the introduction of a variety of explanations (e.g., matching rules), which differ widely in the range of their applicability. That is, some are specific to a particular set of materials while others seek to explain a larger range of reasoning behavior. What has rarely been investigated is the influence of the situational niche on performance, or, more specifically *how is the task itself contributing to the response pattern?* For example, take two contrasting approaches: in one, specific knowledge is required to solve a problem, and in the other, abstract rules (excluding the influence of knowledge) are used to solve problems. Problem A is given in which a substantial amount of content knowledge is given that is relevant to a solution. In this case, we would expect the knowledge-based approach to be better suited to solving this problem. If however a different problem were given in which no background information is provided, then we would predict that the second solution is more likely to be used. We suggest that a strategy approach allows flexibility in explanation by allowing for an individual to display a range of possible approaches to a problem set.

The logical strategy approach is in stark contrast to unified approaches in which explanations for processing logical statements are confined to one approach. A possible criticism at this point is that a unified approach is more parsimonious than a strategy approach. That is, why suggest a series of competing strategies, each of which demands cognitive resources, when one approach would suffice? We provide two responses. First, current unified approaches have been unable to account for a range of performance without many ad hoc additions. For example, Mental Logic theory suggests that logical inferences are derived nearly

automatically by a set of content-free inferential rules (Rips, 1994; Braine & O'Brien, 1998). In order to explain the effect of familiar content, Mental Logic theory incorporated an additional step in the reasoning process, a pragmatic filter, which determines if a statement is to be considered logical or conversational. In the former, logical inferential rules are applied, while in the latter case less formal conversational inferential rules are applied. The result is that the theory postulates an approach to reasoning that undermines its own primary thesis, that logical inference is a set of content-free rules applied as automatically as syntax.

Second, the strategy selection approach does not require a series of additional resources but can be accounted for by a small set of general-purpose cognitive mechanisms. Within the strategy selection framework a series of strategies can be derived within minimal effort on the part of the cognitive system from the experiences with the environment. For an example, let us return to the example given above. To account for reasoning in situations in which statements are presented without familiar content and reasoning with statements presented with familiar content, a strategy selection framework could account for empirical findings by the use of two strategies. The first does not use formal rules but uses the content to derive a plausible conclusion related to the specific content. In the second (without the presence of familiar knowledge), inferential rules are used because the most salient property of the problem is the relations between elements, not the content of elements. The use of each is specific to the situation in which both are presented.

In the sections that follow we will first outline seven strategies and their corresponding task demands. We will then examine the influence of task demands on their selection. We first state that the following is an incomplete model. There are many possible strategies and we are suggesting a small number in this paper. Second, the description of each is limited by space, thus does not cover the full range of possible applications. Given the nature of these limitations, the model is reasonably articulated for the purposes of the paper.

Token Based (Mental Models)

Overview. The token based reasoning strategy has the following characteristics: 1) information is represented as tokens derived from natural language which correspond to perceptual or verbal instantiations of possible states and 2) "logical" reasoning is achieved not through the application of formal rules but by the creation, inspection, and manipulation of tokens (Johnson-Laird, 1983; Johnson-Laird, Byrne, and Schaeken, 1992).

Outline of Processing/Processing Demands. Logical inferences are derived from manipulations of models rather than by using inferential rules. There are three steps in processing token-based propositions: propositional analysis, models generation, and model use. **Propositional analysis**

refers to language processing and is largely analogous to representing the surface structure of a statement and requires sufficient verbal/spatial working memory to encode and parse language. **Model generation** refers to the creation of tokens derived from the propositional analysis and relevant information in the existing knowledge base and in the environment. Generation requires verbal/spatial working memory space to create and hold tokens. **Model Use** is the process of searching and evaluating the set of models created by the procedures outlined above and requires a sufficient processing capacity to create veridical models of the necessary information, creation and search for counterexamples, and evaluations of truth-values. The primary limitation on processing is the working memory space required to create and search models for a solution.

The token-based strategy seems particularly useful in the solution of problems in which there are spatial relations because token-based representations can encode such relations more easily than propositional representations (Johnson-Laird, 1983, 1999). For example, in the transitive problem "Bill is to the right of Fred, Fred is to the right of Sam, Is Sam to the right of Bill?") A token based-representation would easily encode the relevant dimensions as follows:

[Sam] [Fred] [Bill]

An obvious limitation of this strategy is that the number of models needs to remain within the current working memory limitations of the reasoner.

Verbal (Mental Logic)

Overview Verbal logic approaches explain logical reasoning as the result of content-free, logical transformation rules applied to linguistically derived mental structures (Rips, 1994; Braine & O'Brien, 1998).

Outline of Processing in Verbal Theories The core elements of verbal theories share basic processing characteristics. Input is represented and processed in a verbal form (e.g., predicate-argument structures; Braine & Rumain, 1983). Sufficient verbal working memory is required to extract the formal elements and hold the representation in a predicate argument structure. **Application of Transformation Rules** are content-free rules represented as either condition-action pairs (Rips, 1994) or as inferential schemas (Braine & O'Brien, 1997). Once verbal input is represented, the content matches a series of transformational rules that produce an output that is either in the form of a conclusion, a statement that will be operated upon by additional rules, or a statement that does not match additional rules. Errors in processing are attributed to a failure in applying the appropriate rule to the statement.

The verbal strategy is most useful in solving abstract statements in which the focus is on relationships between

elements. For example, in a version of the Wason selection task the card content is related only by formal structure, not by content (e.g., If there is a vowel on one side, there is an odd number on the other side).

Knowledge Based Heuristics (KBH)

Heuristics are rules that do not utilize logical algorithms. Such a strategy does not generate a valid conclusion but may generate "logic-like" performance (Cheng & Holyoak, 1985). KBH are easily implemented processing rules that use *content* as the basis for deriving a conclusion. Unlike algorithmic approaches (e.g. verbal strategy), these conclusions are not necessarily valid (often violating logical inference rules), yet are often pragmatically supported. An example is Pragmatic Reasoning Schemas (PRS; Cheng & Holyoak, 1985) in which social (permission rules) and physical (causality) regularities form the basis of a series of inferences schemas.

Outline of Processing in KBH

There are three processing steps in KBH: **parsing sentence**, **detection of relations**, and **solution output**. Sentence parsing refers to sentence comprehension and includes verbal and nonverbal information. The detection of relations occurs when the present content is similar to content for which there are established rules. For example, in permission relations, there are established rules (typically phrased as conditionals) that suggest appropriate responses. Matching content allows rules to be accessed. Once rules are accessed, they are applied to the specific situation and a solution output is produced.

The detection of specific relations determines if a statement matches an existing schema. Cues such as temporal sequence suggest obligatory or causal relations between elements. For example, in the statement "Mow the lawn and I will give you five dollars" the condition is set in the first clause while the consequent is set in the second clause. Previous knowledge of other exchanges (in which transactions are made on the basis of obligations) forms the basis of these inferences.

Matching Heuristics

Overview- Matching heuristics are selective processing strategies in which solutions are derived based on superficial elements such as terms or common elements (rather than on content as in KBH). Two well-known examples of matching heuristics are Matching biases and Atmosphere effects (Evans, 1989; Woodsworth & Sells, 1935).

Outline of Processing in Matching Heuristics

Matching heuristics specify rules of *selective processing* differ from all previous strategies in that no specific inferential content is accessed. These rules follow a basic processing model as follows: 1) **encode surface structure**, 2) **find key elements**, and 3) **match key elements**. For

example, in the Wason selection task, subjects prefer to choose cards named in the rules rather than cards that are not named in the rules (Evans, 1972). In the first processing step, the subject encodes the surface structure focusing on the elements in the rule. Most likely this involves encoding an IF → THEN rule. The key elements are identified. For example, given "If an odd number on one side, then a vowel on the other side" the subject may focus on "odd number" and "vowel" as key elements. Then, when searching possible solution states, the subject will attend to those solution states that contain the key elements. Continuing with the example above, the subject may be more likely to select a card with an odd number and a card with a vowel because they match elements in the rule. This general processing model also applies to atmosphere effects.

Task-Specific Procedures

Overview- Like heuristic strategies, Task-specific procedures are non-logical procedures that achieve correct solutions on logical tasks without the use of formal inferential rules. Task-specific procedures are reasoning "short-cuts" that produce procedural solutions without declarative understanding. The limitation of TSP procedures is that they do not generalize beyond the specific type of reasoning format in which they were induced. Logical training (education and training studies) may produce these procedures leading to an understanding of logical reasoning analogous to the understanding of Chinese attributed to the occupant of the Chinese room (Searle, 1990).

Outline of Processing in Task-Specific Procedures

The processing demands in task specific procedures can be defined as two steps: (1) encoding the relevant problem features and (2) implementing the appropriate algorithm. For example, in a syllogism evaluation subjects concluded that any syllogism with two "somes" in the premises was invalid (Gallotti, Baron, & Sabini, 1986). Implementing a solution algorithm requires sufficient working memory to hold the encoded premises and to fire the appropriate algorithm.

Pragmatic Acquiescence

Overview- Pragmatic acquiescence (PA) refers to response patterns that are attempts to match the expectations of the questioner. In a situation in which someone has little prior knowledge, they may be inclined to seek social cues from the questioner as to how to respond to a novel situation. Rather than matching the conceptual features of the problem as in matching heuristics, PA-based solutions are based on the pragmatics of the problem/testing situation.

Outline of Processing PA- The PA strategy is used when (1) the pragmatic cues are most salient or (2) other strategies fail to produce a definitive solution.

The first step is encoding relevant cues. We suggest at least four such cues: a) speaker status, b) language cues, c)

intonation cues, and d) gesture cues. Speaker status should influence acquiescence in the following ways: the validity of the response should increase as the authority of the speaker increases. This also suggests an informal metric for calculating the status of self and speaker. Language cues may be the most obvious and suggest the type of response that is expected (e.g., "don't you agree"). The second step is inferring possible solutions based on relevant cues. Selecting the PA strategy should occur when other strategies fail to match or when the pragmatic cues are most salient. In both cases, this suggests that the reasoner lacks the knowledge necessary to solve the problem at hand.

The final step is producing a solution. In this case, the reasoner has encoded relevant cues and determined the cued response. This response is given under any of the following conditions: 1) if no other strategy matches, 2) if a strategy produces a solution that is in conflict with the cued response and fails to override this solution, or 3) if the cued response is so highly activated that it overrides all other strategies.

Retrieval

Overview- Retrieval is accessing a previous solution from long-term memory. Retrieval differs from all other proposed strategies in that it is the only strategy that does not create an on-line solution. We include this strategy because solutions, once discovered, can be accessed from memory rather than creating a new solution each time the same problem is presented. Access to solutions will vary by the time interval between discovery and access (recency), the number of times the solution is accessed (frequency), and the degree to which the current problem state is similar to the problem state associated with the solution (fit). Guessing is a loosely constrained form of retrieval in which a response is produced on the basis of inaccurate or irrelevant information.

Outline of Processing in Retrieval- As suggested above, retrieval of previous solutions depends on a variety of factors. The most crucial is the number of possible matches to the current problem. IF there is only one match, then retrieval is simple. Because there are often several possible solutions to a particular problem, in order to retrieve a solution, there must be a mechanism to determine which of these possible solutions will be accessed at any given time, or conflict resolution. We suggest three mechanisms. The first is recency, or the time between when a solution has been discovered and the time it is accessed (Anderson & Lebiere, 1998). The second factor is the frequency of access. The number of times a solution is accessed increases the base activation level of the solution. The higher the base level of activation, the more likely it is that a particular solution will be accessed. The third factor is the degree to which the problem state linked to a solution state is similar to the current problem state, or fit. The degree of fit will determine which of a set of possible solutions is most similar to the current problem state.

Task Characteristics and Situational Niches

The previous section outlined the processing steps for each strategy. As stated in the introduction to the paper, the probability of a particular strategy being used is a function of the processing demands of the strategy and the situational niche. The following section will outline possible task demands, processing demands and how these factors may be related to the application of specific strategies.

The situational niche is similar to Todd & Gigeranzer's (1999) notion of ecological rationality. Both approaches are derived from Simon's (1957) concept of bounded rationality in which reasoning proceeds on the basis of limited information and both are content-sensitive, in that the type of reasoning response is a function of the task demands. While ecological rationality seeks the most adaptive decision/judgment within an open system (i.e., one in which a correct decision is indeterminate), a situational niche represents the current context in which reasoning is occurring and is a match between the processing demands of the system and the task demands of the problem within a closed reasoning system. Thus in a situational niche a correct solution is possible.

The degree to which a problem is familiar will influence the use of a particular strategy. Familiarity is contrasted on two dimensions, the familiarity of the content and experience with a particular problem type. The degree to which content is familiar should increase the probability of knowledge-based strategies. For example, it is a well-documented finding that an invalid syllogism with a believable conclusion is more likely to be accepted as true than a valid syllogism with an unbelievable conclusion (Evans, Barston, & Pollard, 1983). In this case the familiarity of the conclusion may be the most salient element, thus the element most likely to elicit a strategy match. In the case of less familiar materials, for example a syllogism with two "somes" in the premise, a reasoner may rely on a task-specific heuristic to derive a conclusion (Gallotti, Baron, & Sabini, 1986). When given a series of unfamiliar, abstract materials a reasoner may rely strictly on the formal elements of inference. For example given the abstract version of the Wason task, a reasoner may be unable to derive a series of valid conclusions (e.g. *modus tollens*) but only able to infer *modus ponens* (Wason & Johnson-Laird, 1972). In each of these cases the familiarity of content may change the problem's situational niche, resulting in different probabilities of matching a given strategy.

In the second sense of familiarity, strategy selection may also depend on the degree of experience a reasoner has with the specific problem type. If a reasoner has a great deal of experience with the specific problem type, they are more likely to retrieve a solution or use the same strategy as used on previous trials. As experience decreases, strategy selection is more likely to be a function of other factors in the situational niche (e.g., presentation format). Strategy

selection will be influenced by previous experiences with the problem type and the nature of their outcome associated with the use of *a priori* strategies.

The presentation format also may influence the strategy selected for a particular problem. Presentation formats may be verbal, written, or visual. The type of representation may illustrate or obscure problem characteristics crucial to a correct solution (Larkin & Simon, 1987). Perhaps differences in solutions differ as a function of both the situational niche and the strategy that matches this niche.

In order to illustrate possible links between strategy selection and situational niche, we present the following example. Imagine a transitivity problem in which the basic instructions are given as follows:

Four people are waiting in line at a movie theater with a new seating policy. The new policy states that in order to allow everyone to see the screen, all patrons have to be seated by height. That is, shorter patrons are seated near the front while taller patrons are seated near the back. Five people, Homer, Marge, Bart, Lisa, and Maggie are going to the theater. Based on their relative height (including hair), place them in proximity to the screen.

Knowledge of the source material may influence the type of strategy used. A reasoner with a great deal of knowledge of the source material (The Simpsons®) may simply retrieve a solution (high content familiarity). One who cannot simply retrieve a solution may use their knowledge to match the task constraints as in a knowledge-based heuristic. In this case, the reasoner may be able to place a few members of the family in order without a transitive inference.

Those with no knowledge of the television show may need to solve the problem using different strategies that may depend on the presentation format. If presented pictorially, the representational format reduces the amount of information in working memory and allows a solution to be derived from scanning the relative heights from the visual array (see Figure 1).

Figure 1

If presented verbally, the task can be simplified by ordering the information to align with task demands. For example, if presented in an ordered format (as in Example 2), a simple scan of relations may allow a solution to be derived. In this case, a matching heuristic may be devised in which the tallest person is only on the left side of the text. From here relations are structured after the tallest has been identified.

Example 2

Homer is taller than Lisa.
Marge is taller than Bart.
Homer is taller than Bart.

Bart is taller than Lisa.
 Lisa is taller than Maggie.
 Marge is taller than Homer

When terms are randomly distributed in text (i.e., ordering is not aligned with task demands) then each element must be encoded and compared to all other components requiring greater working memory resources (see Example 3). Such a presentation format may best match a token-based strategy, in which pictures are easily represented spatially as a series of tokens.

Example 3

Homer is taller than Lisa. Bart is taller than Lisa. Marge is taller than Bart. Homer is taller than Bart. Lisa is taller than Maggie. Marge is taller than Homer

The previous examples suggest a link between task demands and processing resources. But how do task demands and processing demands produce strategy selection? Differences in processing demands and task demands will lead to differences in the salience of problem elements. Previous strategy use influences the probability that a given strategy will be used. Using this framework, we may be able to explain both inter- and intra-individual change. For information about competition between existing strategies, we will examine data on one example of errors in logical reasoning: performance differences based on the presence of familiar content. In verbal strategies, errors in processing are attributed to a failure in applying the appropriate rule to the statement. There are at least two conditions under which a rule is unavailable for processing. **Failure to retrieve** a rule suggests that although the rule is present in long-term memory, it is not retrieved for processing the current information. **Failure to match** a rule is typically explained by the presence of content effects (Braine & O'Brien, 1998). That is, when the content is either familiar or supports an inference beyond that of the statement's form, then rule matching is either suppressed or may match a different rule (Rips, 1994). Although failure to match has been cited as a condition under which abstract rules fail to apply, it is plausible that under these conditions knowledge-based heuristics are more likely to be applied, resulting in slightly different conclusions. Conversely, knowledge-based heuristics rules often fail to fire when given abstract elements (e.g., If A, then B) and are restricted to induced relations (i.e., obligation and permission) (Cheng & Holyoak, 1985; Rips, 1994). In both cases, there are ranges of results that cannot be explained by each unified theory, however, viewing each as a strategy allows the inclusion of the seemingly conflicting empirical findings into a single model.

The strategy approach maintains the explanatory power of each theory while increasing the scope of explanation. The strategy approach accounts for a range of results by suggesting that each strategy possesses distinct processing demands that are likely to match the task demands of specific problem. By allowing multiple approaches within

individuals across time the strategy approach is maximally flexible allowing the possibility of explaining differences across tasks and individuals.

Commonalities and Distinctions in Featural Stimulus Representations

Daniel J. Navarro and Michael D. Lee
{daniel.navarro, michael.lee}@psychology.adelaide.edu.au
Department of Psychology
University of Adelaide SA 5005, Australia

Abstract

This paper evaluates four featural models of stimulus similarity using data collected for a set of 16 nations. Algorithms are developed for finding stimulus representations, and the important issue of balancing data-fit against model complexity is addressed by using the Geometric Complexity Criterion. Although the data clearly incorporate both common and distinctive features, Tversky's (1977) Contrast Model seems unable to express these regularities in an appropriate manner. However, we show that a new version of the Contrast Model that treats each feature as either being common or distinctive is better able to capture the essential aspects of the similarity judgments.

Featural Representation

A fundamental issue in psychology regards the appropriate manner in which to represent stimuli in a model of human cognition. As argued by Brooks (1991), it is important to constrain representations to those justified by empirical data, and avoid the questionable practice of specifying representations "by hand". One well-established technique for pinning down mental representation involves measuring the similarity between pairs of stimuli. The assumption underlying this approach is that the decision process involved in judging similarity is a simple one, and thus the data can be considered to reflect the underlying mental representation to a large extent. While this is not without theoretical difficulties (e.g., Goodman, 1972; Goldstone, Medin, & Halberstadt, 1997), it is substantially superior to the alternative approach of hand-tuning representations, which may not reflect human representational structures in any regard. Goldstone's (1999) recent review identifies four main approaches to similarity modeling: geometric, featural, alignment-based and transformational. In this article we discuss current approaches to featural representation, and provide experimental evidence to support a new approach for modeling featural similarity.

The featural approach to mental representation describes an object in terms of the attributes it possesses. Features may be either perceptual or conceptual in nature: for example, a tiger might possess the features "four legged", "orange", and "predatory".

The task of deriving featural representations from similarity data can be stated as follows: if n denotes the number of stimuli in the domain, then given an $n \times n$ matrix of similarity judgments S , find a set of m features that explain these judgments. We can denote this set of features by the $n \times m$ feature matrix $F = [f_{ik}]$, where f_{ik} is 1 if the i th stimulus possesses the k th feature, and 0 if it does not.

Four Models of Featural Similarity

One well-established approach for extracting featural representations from similarity data involves using additive clustering algorithms (e.g., Shepard & Arabie, 1979; Tenenbaum, 1996). The similarity between two stimuli is estimated as the sum of the weights of their common features (i.e., those that they both possess). That is,

$$\hat{s}_{ij} = \sum_k w_k f_{ik} f_{jk} + c, \quad (1)$$

where w_k denotes the saliency weight of the k th feature, and c is a positive-valued constant added to all similarity estimates. Thus an m -feature common features representation consists of the feature matrix F , the vector of saliency weights $\mathbf{w} = [w_1, w_2, \dots, w_m]$ and the additive constant. As noted above, additive clustering relies on a purely common features model. This means that the stimuli become more similar only to the extent that they share features.

An alternative featural model is the distinctive features model, under which similarity is measured according to the differences between the features that stimuli have. This means that if one stimulus has a feature and another does not, they become less similar. This can be written as

$$\hat{s}_{ij} = c - \frac{1}{2} \sum_k w_k f_{ik} (1 - f_{jk}) - \frac{1}{2} \sum_k w_k (1 - f_{ik}) f_{jk}, \quad (2)$$

which is identical to the symmetric distance metric proposed by Restle (1959), and closely related

to discrete multidimensional scaling (Clouse & Cottrell, 1996; Rohde, in press).

A general framework that interpolates between these two models is Navarro and Lee's (2001) adaptation of Tversky's (1977; Gati & Tversky, 1984) Contrast Model (TCM), consisting of a weighted sum of the common features similarity (Eq. 1) and the distinctive features similarity (Eq. 2). If we let $0 \leq \rho \leq 1$ denote the weighting given to the common features component, then this model is given by

$$\hat{s}_{ij} = \rho \sum_k w_k f_{ik} f_{jk} - \frac{1-\rho}{2} \sum_k w_k f_{ik} (1 - f_{jk}) - \frac{1-\rho}{2} \sum_k w_k (1 - f_{ik}) f_{jk} + c. \quad (3)$$

The common features model corresponds to the extreme case $\rho = 1$, and the distinctive features model to the other extreme case $\rho = 0$.

However, this model is not the only way of striking a balance between common and distinctive features. Alternatively, we propose a new featural similarity model in which *each individual feature* is declared to be either a common feature (which increases the similarity of pairs of stimuli that share it) or a distinctive feature (which decreases the similarity of a pair of stimuli if one has it and the other does not). This Modified Contrast Model (MCM) is thus:

$$\hat{s}_{ij} = \sum_{k \in CF} w_k f_{ik} f_{jk} - \frac{1}{2} \sum_{k \in DF} w_k f_{ik} (1 - f_{jk}) - \frac{1}{2} \sum_{k \in DF} w_k (1 - f_{ik}) f_{jk} + c, \quad (4)$$

where $k \in CF$ implies that the sum is taken over common features, and $k \in DF$ means that only distinctive features are considered.

Psychologically speaking, the argument is that a feature embodies some kind of regularity about the world, which may be that a set of stimuli all have something in common, or alternatively, that two groups of stimuli are in some way different from each other. A common feature instantiates the idea of "similarity within", whereas a distinctive feature represents the notion of "difference between". While it may be the case that the saliency of a feature can change, a commonality does *not* suddenly become a distinction, nor vice versa. In the MCM, the overall balance between commonality and distinctiveness emerges as a function of the relative number and saliency of common and distinctive features, rather than being specified by the parameter ρ , as it is in the TCM. That is, where the TCM assumes

that common and distinctive features are weighted during the decision process, the MCM considers the commonality or distinctiveness of a feature to be a regularity inherent in the environment, and so embeds it in the representation itself. In this way, the MCM assumes that featural regularities can be either commonalities or distinctions, but never a bit of both. When a group of stimuli have both common and distinctive aspects, the MCM models these two aspects as two distinct featural regularities.

Model Fitting

It is useful to distinguish between the psychological problem of modeling featural similarity and the numerical problem of finding features (Shepard & Arabie, 1979). The psychological problem is: given a set of features F , how should similarities be estimated? This is the question addressed by the four featural models discussed in the previous section. The numerical problem is a data fitting problem: given a set of similarity data S , and assuming a particular psychological model, what set of features F most probably gave rise to the data? A variety of approaches have been adopted in fitting the additive clustering model, ranging from mathematical programming (Arabie & Carroll, 1980) to expectation maximization (Tenenbaum, 1996) and stochastic hillclimbing (Lee, in press). The process by which such algorithms operate is relevant to the psychological problem of similarity modeling only inasmuch as we require that they derive good answers to the numerical problem. While none of the above methods is perfect, it is fair to say that each approach performs well enough to allow interpretation and discussion of the derived representations. The representations derived here used a stochastic hillclimbing approach to fit the featural models similar to that adopted by Lee (in press) and Navarro and Lee (2001).

The fitting procedure adopted the Geometric Complexity Criterion (GCC: Myung, Balasubramanian, & Pitt, 2000) as the measure to be minimized by the successful representation. As has been remarked upon previously (e.g., Myung, 2000; Roberts & Pashler, 2000), achieving a good data-fit is not the sole criterion of a good model. Other considerations such as generalizability, simplicity and interpretability must be taken into account. From a quantitative standpoint, one can operationalize the trade-off between fit and complexity in a kind of formal version of Ockham's razor. The GCC is based on the notion that the complexity of a model is given by the number of distinguishable parametric distributions indexed by the model. Informally, this can be thought of as a measure of how many different

similarity matrices could be produced by a given feature structure under all possible choices of saliency weights. The more distributions a model indexes, the more complex it is. This measure is superior to the Akaike Information Criterion (Akaike, 1977) or the Bayesian Information Criterion (Schwarz, 1978), which estimate model complexity by counting the number of free parameters. As Lee (2001) has pointed out, the number of parameters is not a good indicator of the complexity of featural representations, since the way in which features are assigned to stimuli has a considerable influence on model complexity. Furthermore, Navarro and Lee (2001) have demonstrated that common features representations are more complex on average than distinctive features representations. These systematic differences in what Myung and Pitt (1997) call the functional form complexity of a model require a more discriminating measure such as the GCC. The derivation of GCC measures for the four featural models is straightforward, and follows the approach outlined by Navarro and Lee (2001).

Experiment

In order to provide an empirical test of the four featural similarity models, similarity data were collected for a set of 16 nations identified by name. The nature of this domain made it less than satisfactory to present people with a pair of countries and ask them to rate their similarity. It seems likely that this task would be ambiguous, in that the initial reaction of participants may be to ask, "Compared to what?" Even when the similarity between a pair of nations does not need a context, participants are unlikely to bring to this task a pre-existing numerical scale of nation-similarity upon which to rate it. An alternative approach is to provide participants with a context in which to make judgments. The task we used was to present people with a list of four countries, and ask them to select from the list the pair of nations most similar to one another.

Method

Participants Participants in the study were 16 university students (4 male, 12 female) aged 17 to 36, with a median age of 24, who took part in the experiment for course credit.

Materials The list of nations used was: China, Cuba, Germany, Indonesia, Iraq, Italy, Jamaica, Japan, Libya, Nigeria, the Philippines, Russia, Spain, United States, Vietnam, and Zimbabwe. They were chosen to suggest a variety of possible classification schemes (e.g., political system vs geographical location), and involve a variability in over-

all saliency (e.g., Italy and Germany were better known to most of our participants than Zimbabwe and Nigeria).

Procedure On each trial a list of four countries was displayed (via computer) to the participant, who was asked to pick out the two countries most similar to each other. The 16 nations yield $\binom{16}{2} = 120$ distinct pairs of nations, and a total of $\binom{16}{4} = 1820$ possible lists of four. Given that the similarity ratings are sensitive to all four presented stimuli, it was important to exhaust exactly the set of 1820 quadruples. To that end, the 1820 items were partitioned into 20 subsets of 91 quadruples. Most participants provided responses to one of these subsets, though a few of the participants provided responses to multiple subsets. Since each quadruple involves the presentation of 6 of the 120 nation-pairs, each pair appeared a total of $\frac{1820 \cdot 6}{120} = 91$ times across the entire data set.

Results

Calculating the mean empirical similarity involved operationalizing the similarity of a pair of countries as the expected probability of selecting that pair in an arbitrary trial containing both stimuli. Using a standard result in Bayesian statistics (Gelman, Carlin, Stern, & Rubin, 1995, p. 31), if a particular pair is chosen k times out of n (n being 91), then the empirical similarity is given by $s_{ij} = \frac{k+1}{n+2}$. In using the GCC to control model complexity, it is important to know the precision of the similarity values (Lee, in press), which is basically a measure of the extent to which participants agreed in their judgments. Precision is important because more precise data justify more complex models. We estimated the precision to be moderate, by using the full distribution of the similarity judgments. Details of this estimation procedure, as well as that used to calculate similarity values, are given by Navarro (2002).

Using our stochastic hillclimbing algorithms, representations of the nations similarity data that minimized the GCC were found for each of the four similarity models. Of these four representations, the GCC values for the common features, distinctive features, and MCM representations are virtually indistinguishable, with the TCM performing slightly better. However, the qualitative characteristics of these representations are important in terms of model interpretability, and we discuss each in turn.

The best common features representation is shown in Figure 1, and contains seven features that explain 78.1% of the variance in the data. The features are highly interpretable, containing features for western European nations, Caribbean nations, south-

Figure 1: Common features representation of the nations similarity data, accounting for 78.1% of the variance (GCC=41.2). Common features are depicted by rectangles that encompass the nations that possess them.

ern African nations and Asian nations. It seems probable that the feature containing only the Philippines and Indonesia reflects perceived cultural and geographical similarities, and that the Iraq-Libya feature reflects the fact that both are Arabic nations and that both have been considered "rogue states". The final feature consists of Germany, Russia, United States, China and Japan, and could be said to denote the "world powers" among the stimulus set.

The best distinctive features representation is shown in Figure 2, and contains five features that explain 71.0% of the variance in the data. Three of the five features have a natural interpretation: one feature separates the African and Middle-Eastern nations from the rest of the world, and another separates the Asian nations from the others. The top-weighted feature in Figure 2 makes an intuitively plausible distinction that might be labeled "developed vs undeveloped". It is interesting to note that the placement of China within the developed nations is equivocal, since the GCC increases only marginally when China is placed in the other category. This makes sense, given China's status as a quickly developing nation. Significantly, however, the remaining two features do not appear to reflect any kind of interpretable structure. From a psychological standpoint, this is highly undesirable, since a central aim of representational modeling is to find interpretable structures in the data.

Table 1 displays the six feature representation derived using the TCM with $\rho = 0.7$, which explains 80.8% of the variance. Since the TCM specifies a

Figure 2: Distinctive features representation of the nations similarity data, accounting for 71.0% of the variance (GCC=41.5). Distinctive features are depicted by lines that partition the stimulus set.

balance of common and distinctive features, there is no simple way of depicting this representation graphically. The high ρ value indicates that commonalities are weighted more heavily than differences. All of the clusters in Table 1 appear in either the common features or distinctive features representations, which is not surprising. The features themselves make sense, although it is not easy to see exactly what $\rho = 0.7$ means when providing an overall interpretation. It is noteworthy that the distinctive feature that separated the developing from developed world in Figure 2 does not appear in this representation, despite being the most heavily weighted of the distinctive features. The reason for this may be that the feature does not make sense as anything other than a purely distinctive feature, since any common features component makes one half (either developed or developing) more salient than the other.

The seven feature MCM representation shown in Figure 3 explains 81.2% of the variance, and picks out a number of features from the common features representation: the western Europe, Caribbean, southern Africa and Asian features are all present, as is the "world powers" feature. The feature containing Cuba, Iraq and Libya is interesting, in that the inclusion of Cuba is a marginal case as judged by the GCC. With Cuba included, the feature has a "rogue states" interpretation, whereas without Cuba it would reflect the Arabic nations. Finally, the model also includes the "developed vs developing" regularity from the distinctive features representation. The comparison between this distinctive feature and the "world powers" common feature is also worth making. The fact that these two related but

more than two groups. For example, the notion that a thing is "animal", "mineral" or "vegetable" could be considered to be distinctive feature that partitions the stimuli into three groups. Moreover, there is a case to be made for representational formalisms that involve both discrete aspects (such as features) and continuous aspects (such as spatial dimensions). Accordingly, another avenue for research would be to pursue hybrid models that involve spatial as well as featural components.

Thinking by Doing?

Epistemic Actions in the Tower of Hanoi

Abstract

This article explores the concept of epistemic actions in the Tower of Hanoi (ToH) problem. Epistemic actions (Kirsh & Maglio, 1994) are actions that do not traverse the problem space toward the goal but facilitate subsequent problem solving by changing the actor's cognitive state. We report an experiment in which people repeatedly solve ToH tasks. An instructional manipulation asked participants to minimize moves either trial by trial or only on the last three of six trials. This manipulation did not have the predicted effect on the trial-by-trial move counts. A second, device manipulation provided some participants with an "exploratory mode" in which move sequences could be tried then undone without affecting the criterion move count. Participants effectively used this mode to reduce moves on each trial, but there was no clear evidence that they used it to learn about the problem across trials. We conclude that there is strong evidence for one sub-type of epistemic action (acting-to-plan) but no evidence for a second sub-type (acting-to-learn).

Introduction

How do we learn to solve a problem? The most popular view within the Cognitive Science community is that we do so by solving the problem. Anzai and Simon's (1979) theory of 'learning by doing' marks a major breakthrough in research on learning through problem solving. They proposed an adaptive production system which mirrored the strategy transformations of a human participant as she solved the Tower of Hanoi (ToH) problem, and in so doing provided the impetus for many subsequent theories of the mechanisms by which problem solving leads to learning (e.g. Klahr, Langley & Neches, 1987).

All learning-by-doing accounts share the assumption that learning about a particular problem occurs as an automatic by-product of problem solving activity. However, in many problem solving situations learning may be more deliberate than the learning-by-doing account implies. We suggest that problem solvers may sometimes orient themselves to *learning goals* rather than *solution goals* (O'Hara & Payne, 1998; Trudel & Payne, 1995).

In relation to the ToH task, this position is encouraged by VanLehn's (1991) re-analysis of the original Anzai & Simon (1979) protocol, in which he notes that the participant was "acting like a scientist" (p. 16) and repeatedly suspended her problem solving activity to acquire new strategic knowledge.

Further general support for a deliberate learning mode nested within problem solving activity can be derived from the work of Kirsh and colleagues (1995, Kirsh & Maglio, 1994), who have explored a distinction between goal-directed *pragmatic actions* and *epistemic actions* whose primary purpose is to improve cognition by changing an agent's computational state. Although epistemic actions are not immediately goal-directed, they may improve subsequent performance through their cognitive effects.

The primary goal of this article is to seek experimental evidence for the use of epistemic actions in problem solving with the ToH puzzle. Identifying epistemic actions in ordinary problem solving activity is difficult, because they are only distinguished by their cognitive motivations and consequences rather than directly observable characteristics (and not all actions that do not successfully move toward the goal are epistemic!). We use two manipulations that may allow participants to utilise epistemic actions, and at the same time facilitate their detection. The first manipulation is *instructional*: participants were asked either to optimize their performance on every problem solving trial, or on trials 4, 5 and 6 of a series of six repeated problems. We hypothesize that delaying the enforcement of the performance criterion will encourage a learning orientation, and the use of epistemic actions, during the early first trials. The second manipulation is to provide *device support* that enables participants to separate pragmatic from epistemic actions. Thus, our computer-based version of ToH allowed participants to switch into an "exploratory mode" in which they could make move sequences that were later undone and were not counted towards the performance criterion.

These twin manipulations allow us to refine Kirsh's formulation of pragmatic and epistemic actions by distinguishing between two kinds of epistemic action: those that have only immediate within-problem effects (*acting-to-plan*) and those that have longer-term cognitive consequences (*acting-to-learn*). If the exploratory mode is used merely as an external support for look-ahead or planning, motivated by questions such as 'Is this a good sequence of moves?', we would regard such usage as acting-to-plan. On the other hand, if additional actions on earlier trials are shown to lead to better problem solving on later trials we would have evidence for acting-to-learn.

To anticipate our conclusions, we find strong support for acting-to-plan, but no decisive support for acting-to-learn.

Method

Participants

Forty-four Psychology undergraduates (with a mean age of 20.7 years) took part in the experiment to receive course credit. Participation was restricted to first year undergraduate students who reported no prior exposure to the task. All participants were familiar with graphical user interfaces and did not suffer from any perceptual or cognitive impairments.

Apparatus

The experiment used a graphical software version of the ToH problem which was programmed in Visual Basic 6 and displayed on a 17" screen. A disk could be transferred between towers by indicating its source and target locations using a drag-and-drop procedure. In case of an illegal move there was an auditory warning signal and the selected disk slid back to its original position. A counter showing the current number of pragmatic moves was displayed in the top right hand corner of the screen.

Materials

Participants had to solve a sequence of 5-disk ToH puzzles in the standard tower-to-tower version. To prevent improvements due to superficial rote memorization we used six simple isomorphs, which were created by systematically switching the source and target towers.

Design

As we wanted to test participants' *spontaneous* use of epistemic actions we did not want to specifically encourage them to explore the problem, but rather provide subtle opportunities that may be used or ignored.

The *instructional manipulation* consisted of two levels. Participants were either instructed to optimize their performance (i.e., minimize the number of pragmatic moves needed to solve the puzzle) on each of several problems, or asked to optimize their performance on the last three of six problems. Hence, whereas the first group of participants was implicitly discouraged from using epistemic actions by the instruction to be *performance oriented* throughout an unspecified number of trials, the second group was presented with an opportunity to be *learning oriented* in the first three of six trials.

The second experimental manipulation consisted in withholding or providing *device-support* for epistemic actions. Two different versions of the device were distinguished:

In the standard *pragmatic moves only* condition, each move of a disk on the screen counted towards the performance criterion of minimizing the number of (pragmatic) moves.

Device-support	Instruction
1. pragmatic mode only	'minimize on trials 1-6'
2. pragmatic mode only	'minimize on trials 4-6'
3. pragmatic+epistemic mode	'minimize on trials 1-6'
4. pragmatic+epistemic mode	'minimize on trials 4-6'

Table 1: Overview of the two experimental factors and four groups.

In a second *pragmatic plus epistemic moves* condition two different device modes were introduced to the participants. Whilst having to solve the puzzle in so-called "solution mode", participants had the option to switch into an "exploration mode" at any point by pressing and holding down the Shift key. Whereas in both modes disks could be moved in an identical fashion, moves made in exploration mode were not added towards the total performance score and always reversed when switching back into "solution mode" by releasing the Shift key.

Note that the specific design of exploratory mode addresses the difficulty of detecting epistemic moves by effectively creating an *operational definition*: Since participants are aware of the mandatory reversal of all moves made in exploratory mode, entering the mode signals the use of epistemic moves.

One way of characterizing both the instructional and device manipulation is that they do not prevent learning by doing, but provide additional opportunities for *learning by not solving* the puzzle. A combination of both experimental factors yielded the four experimental groups shown in Table 1.

As each participant had to solve a total of six ToH puzzles the experiment employed a mixed design, with *device-support* and *instruction* as between-subjects manipulations and *trial* as a within-subjects factor.

Procedure

Each participant was assigned to one experimental group according to the order of arrival at the laboratory. After reading a generic description of the Towers of Hanoi puzzle participants were introduced to the graphical user interface. To demonstrate that they had understood the task constraints and to familiarize themselves with the user interface they solved a simple two-disk version of the puzzle.

Participants then received their respective minimization instructions and were told that the experiment normally takes around 45 minutes regardless of their individual performance.

After each successful completion of a problem, participants received a brief message reminding them of their respective minimization instruction before starting the next trial.

On average, participants completed the experiment within 40 minutes.

Predictions

Our primary predictions refer to comparisons between and within experimental groups (rather than assuming a 2x2 factorial design; in particular Group 4 plays a subsidiary role in the study, and will only be analysed in relation to first-order findings).

The main predictions concern the number of pragmatic moves needed to solve the puzzle. As we expect all groups to learn throughout the course of the experiment, we predict a gradual reduction of the mean number of pragmatic moves required to solve the puzzle. This familiar practice effect constitutes the baseline which we expect to be modulated by the experimental factors of instructional goal orientation and device support.

If the instructional manipulation encourages members of Group 2 to invest additional moves in trials 1–3 and this in turn results in better learning, they ought to need fewer moves on trials 4–6. Thus, we predict an *interaction* of instruction and trial for Groups 1 vs. 2.

Next, if participants are spontaneously capable of using the exploratory device mode to improve their performance, Group 3 should need fewer pragmatic moves than Group 1 in all trials. Hence, we predict a *main effect* of device support on the number of pragmatic moves for Groups 1 vs. 3.

Our secondary predictions involve Groups 3 and 4 and address different possible motivations for epistemic moves:

If the exploratory device mode is primarily used for *learning* purposes (acting-to-learn) we should find an instant use of epistemic moves in both Group 3 and 4. If learning actually occurs, the frequency of epistemic moves should decrease over time. If, on the other hand, epistemic moves are used primarily for *online planning* within a trial (acting-to-plan) we expect a more opportunistic use due to the instructional manipulation. In this case, we expect the frequency of epistemic moves in Group 3 and 4 to display an *interaction* over trials.

Finally, if the use of epistemic mode is unselective, and predominantly due to *affordances* created by the design of our device we should find a constant use of epistemic moves throughout all trials and similar usage patterns in Groups 3 and 4.

Results

Numbers of Moves

As all groups were instructed to minimize the number of moves to solve the ToH puzzle our comparative analysis of their performance will be based on the number of pragmatic moves per trial.

Overall learning effects Before we consider the comparisons between individual groups, we will examine the expected overall effects of learning. Figure 1 displays the mean number of pragmatic moves for each group from trials 1 to 6. A mixed ANOVA of pragmatic moves with *group membership* as between-subjects factor and *trial*

Figure 1: Mean number of moves for each of the four groups on each of six trials. For Groups 1 and 2 the number of pragmatic moves corresponds to the number of total moves, whereas Groups 3 and 4 had the option of making epistemic moves in addition to pragmatic moves. (Note: The minimum possible number of pragmatic moves to solve the task is 31.)

as within-subjects factor confirms the overall learning effect [$F(5,200)=16.3, p=.000, MSE=260.4$] and indicates that there were differences between groups [$F(3,40)=5.8, p=.002, MSE=489.2$], but the interaction between the two factors did not reach significance [$F(15,200)=1.5, p=.13, MSE=260.4$].

Whether an individual group has significantly improved over time can be assessed by conducting simple effect tests within groups by trial. These show that Groups 1, 2 and 4 significantly reduced their number of pragmatic moves over the course of the experiment. The means for Group 3 were low even at the first trials, suggesting that it did not improve significantly because it consistently performed at a high level.

On trials 4–6, in which all groups were instructed to minimize the number of pragmatic moves, both Group 2 and 3 outperformed Group 1 by taking fewer pragmatic moves ($p=.003$ and $.008$ respectively).

Thus, the overall results seem promising: With respect to the performance criterion Groups 1, 2 and 4 improved over time and Groups 2 and 3 managed to solve the ToH puzzle in fewer moves than Group 1 in the second half of the experiment.

Effects of Instruction (Groups 1 vs. 2) Our first specific prediction concerned Groups 1 and 2, neither of which had the epistemic device mode at their disposal, but differed in their instructions: Whereas Group 1 was instructed to minimize the number of moves in each trial, Group 2 was only asked to optimize their performance in

Figure 2: Mean number of moves for Groups 1 and 2 on trials 1–3 and 4–6. (Note: The minimum possible number of moves is 31.)

the last three of six trials. As the scope of this experimental manipulation juxtaposed trials 1–3 with trials 4–6 it is appropriate to collapse the data across each triple of trials by computing the respective means.

Figure 2 shows the mean number of moves for both groups on trials 1–3 and 4–6. It illustrates that there is no hint of the predicted crossover interaction [$F(1,20)=.44$, $p=.51$, $MSE=72.6$]. Instead, the predicted learning effects over both test halves [$F(1,20)=35.4$, $p=.00$, $MSE=72.6$] are combined with an unexpected main effect of group [$F(1,20)=8.1$, $p=.01$, $MSE=119.0$].

While successfully predicting that Group 2 would use fewer moves on trials 4–6 [$F(1,20)=8.9$, $p=.01$] it is immediately obvious that this advantage in performance cannot be attributed to its members using epistemic actions in the initial trials: they clearly have not invested *additional* moves on trials 1–3.

One plausible, if rather annoying explanation for this pattern of data, is that, by an accident of assignment, Group 2 might comprise more able problem solvers than Group 1. (We will briefly consider an alternative account below.)

Effects of Device Support (Groups 1 vs. 3) Groups 1 and 3 shared the same instructions (to minimize the number of moves on each trial) but differed in the options provided by the user interface (device). Specifically, members of Group 3 had the “exploratory mode” at their disposal which supported the use of epistemic moves.

In the overview of the number of pragmatic moves of all four groups we have already established that Group 3 performed better than Group 1 on trials 4–6. A mixed ANOVA of pragmatic moves by group membership and trial confirms the predicted main effect of group over all six trials [$F(1,20)=18.0$, $p=.000$, $MSE=359.9$]. Thus, Group 3 *consistently* performed better than Group 1 with respect to the criterion.

To interpret this difference in performance the number of epistemic moves of Group 3 has to be taken into account as well. (The number of epistemic moves is represented by dotted lines in Figure 1).

If we add the epistemic moves carried out by Group 3 to their pragmatic moves, Group 3 used more total moves on average than Group 1 (mean total moves=68.7 and 55.1 respectively), but this difference is not statistically significant [$F(1,20)=.11$, $p=.12$, $MSE=2165.3$].

This demonstrates that Group 3 spontaneously managed to use the device-supported option of epistemic moves to improve their performance with respect to the criterion. However, it leaves open exactly *why* and *how* members of Group 3 used the exploratory mode. We will address these issues after assessing the effects on solution latency.

Solution Times

Although participants had been told that the total experiment took a standardized length of time—hence could not assume that by being quick or slow they would alter the overall duration of their experimental session—their latencies to solve a problem can be used as an alternative indicator to assess their performance.

Overall effects As one might expect solution latencies over the course of the experiment decreased for all groups. An overall mixed ANOVA on the effects of group membership and trial on the total time required to solve each task yields a main effect of trial [$F(5,200)=16.9$, $p=.000$, $MSE=13352.7$] but no differences between groups. However, a significant interaction of the two factors [$F(15,200)=1.8$, $p=.038$, $MSE=13352.7$] drew attention to the possibility that different groups might have exploited time selectively to optimize their performance.

Subsequent simple main effect tests confirm that while the total solution times of Groups 1 and 3 significantly decreased over repeated trials, this was not the case for Groups 2 and 4. This suggests that the instructional manipulation had a selective effect on solution time, and in particular raises the possibility that the improved performance of Group 2 over Group 1 on trials 4–6 was caused in part by Group 2 exerting greater effort on these trials.

Effects of Instruction (Groups 1 vs. 2) The suggestion that Group 2 outperformed Group 1 in trials 3–6 by exerting extra effort (rather than the hypothesized investment of epistemic moves) is supported by an analysis of *move rates*, i.e. the number of moves made per second. Figure 3 shows the mean move rates of Group 1 and 2 over both test halves. A corresponding ANOVA on move rate by group and test half yields a highly significant interaction [$F(1,20)=18.3$, $p=.000$, $MSE=.002$].

If we interpret an increase in move rate (as seen in Group 1) as signalling the necessity of less effort per individual move, the *absence* of an increase in Group 2 suggests that its members invested relatively more effort in the second half of the experiment.

Figure 3: Mean move rates for Groups 1 and 2 on trials 1-3 and 4-6.

Effects of Device Support (Groups 3 and 4)

One of the questions raised above was: *How did Group 3 use epistemic moves to outperform Group 1?* As the total solution times for Groups 1 and 3 did not differ [$F(1,20)=.38, p=.54, MSE=66525.2$] recourse to latency data does not resolve this issue.

Although the present experiment does not allow us to answer questions about possible causes and effects of device-supported epistemic moves conclusively, we can provide tentative evidence for some of the related issues:

- Did the use of epistemic moves actually lead to *better learning*? The fact that Group 3 *continued to use* epistemic moves until the last trials suggests that they probably did not learn more about the ToH puzzle than Group 1, but used the exploratory device mode as a tool to optimize their performance. However, our design allows for the alternative explanation that the continued use of epistemic moves might have been due to a conservative strategy.
- Did the use of epistemic moves become *more effective over time*? An index of the effectiveness of each epistemic move can be computed by dividing Group 3's mean savings of pragmatic moves (compared with Group 1) by the number of epistemic moves invested on each trial. As the six corresponding ratios (0.5, 0.3, 1.0, 0.2, 1.1, 0.7) do not show any obvious trend, we conclude that the use of exploratory mode did not become more effective over time.
- Were epistemic moves used *to learn or to plan*? Even without evidence for superior learning due to device-support of epistemic moves we can address the question of participants' *motivation* to use exploratory mode by comparing the usage patterns of Group 3 and 4. Figure 4 shows a clear interaction of group membership and test half on the mean number of epis-

Figure 4: Mean number of epistemic moves for Groups 3 and 4 on trials 1-3 and 4-6.

temic moves [$F(1,20)=.54, p=.03, MSE=572.7$]. The same pattern can be observed when we consider the relative frequency of epistemic moves: Whereas the use of epistemic moves for Group 3 decreases over time, members of Group 4 increase their use of epistemic moves in the second half of the experiment. This suggests that exploratory mode was used opportunistically to meet the instructional constraints, i.e., for online-planning (acting-to-plan) on the current trial, rather than as a prospective investment into learning (acting-to-learn).

- Were epistemic moves used because they were available, i.e., was the usage of exploratory mode simply a task-demand like artifact, prompted by our device manipulation? The strategic use of epistemic moves observed by Group 4 attenuates this concern. Rather than being a mere device affordance, exploratory mode was used selectively to achieve online planning.

Discussion

Participants in the exploratory mode conditions spontaneously and effectively used the device-support to achieve a performance criterion, and in so doing they demonstrated capability for using epistemic actions to improve immediate performance.

However, both the observed unwillingness to invest additional moves in early trials and the selectivity of usage patterns suggest that participants were only willing to invest epistemic moves when they stood to gain an immediate benefit from so doing. There was no clear sign of increased learning through use of exploratory mode or willingness to use epistemic moves for learning purposes. Instead, the selective use suggests that epistemic actions were mainly serving the function of look-ahead (acting-to-plan) rather than learning prospectively about the ToH task (acting-to-learn).

Our instructional manipulation did not have the predicted effect. This may have been due to an unfortunate mismatch between the experimental groups, or it may be that our initial hypotheses about an interesting distinction between problem-solving and learning orientations are unfounded, at least for Tower of Hanoi. Perhaps more likely still is the possibility that our instructional manipulation was too subtle to invoke any change in orientation.

In Kirsh's writing on epistemic actions and related themes, which was one of the sources of inspiration for the current study, an additional concept is introduced by contrast with goal-directed behaviour, namely "complementary strategies" (Kirsh, 1995, 1996). It is not clear to us how precise a distinction Kirsh is promoting between "complementary" and "epistemic": indeed there is a hint in his writings of mere terminological evolution. Nevertheless, we suggest that there is an important distinction that might be sketched. As defined above, epistemic actions have their effect by modifying cognitive structures in the actor. By contrast, consider such example complementary strategies as moving coins in order to count them, or marking numbers in order to add them (Kirsh, 1995, 1996; Neth & Payne, 2001). Such operations work by modifying the problem so as to be more compatible with cognitive capabilities, rather than changing the cognitive state of the actor. We agree with Kirsh that complementary strategies of this kind are ubiquitous in human behaviour.

The case for ubiquity is less clear for epistemic actions. In this article we have sketched a distinction between two kinds of epistemic actions, actions-to-learn and actions-to-plan. We have found evidence for the latter, but none for the former.

One reason that acting-to-learn may be relatively less common than complementary strategies and than acting-to-plan, is the success of learning-by-doing. A second reason, ironically, is that acting may sometimes compete with learning. As shown by O'Hara and Payne (1998), and Trudel and Payne (1995), internalising problem solving activity and planning (doing more mental look-ahead or reflection) can itself increase learning in a problem solving context. For example, when exploratory learners had their interactions with a digital watch rationed, they learned more successfully how to use the watch (Trudel & Payne, 1995).

Despite these arguments, we are confident that, as defined in the introduction, actions-to-learn (i.e. actions that are *not* intended to solve the current problem but only to learn about the current problem) are indeed an important aspect of problem solving and learning. However, such actions may be less widely and spontaneously available and harder to study in conventional puzzle-solving domains.

Turning from the philosophical to the practical, one very concrete contribution of the current article is the idea of incorporating an exploratory mode, with instant undo, into the user interface. Undo functions are, of course, well-established and universally acknowledged contributors to device usability (although some thorny

technical design issues are still debated). What is novel about our exploratory mode, we believe, is that it guarantees a very rapid return to particular user-chosen system states. It can accomplish this because the user makes a specific *commitment* to undoing subsequent actions. Although this might seem counter-indicated in mundane HCI contexts, we suggest related designs may be worth pursuing in any domain where people stand to benefit from "thinking by doing".

Bayesian Learning at the Syntax-Semantics Interface

Sourabh Niyogi (niyogi@mit.edu)

Massachusetts Institute of Technology
Cambridge, MA USA

Abstract

Given a small number of examples of scene-utterance pairs of a novel verb, language learners can learn its syntactic and semantic features. Syntactic and semantic bootstrapping hypotheses both rely on cross-situational observation to hone in on the ambiguity present in a single observation. In this paper, we cast the distributional evidence from scenes and syntax in a unified Bayesian probabilistic framework. Unlike previous approaches to modeling lexical acquisition, our framework uniquely: (1) models learning from only a small number of scene-utterance pairs (2) utilizes and integrates both syntax and semantic evidence, thus reconciling the apparent tension between syntactic and semantic bootstrapping approaches (3) robustly handles noise (4) makes prior and acquired knowledge distinctions explicit, through specification of the hypothesis space, prior and likelihood probability distributions.

Learning Word Syntax and Semantics

Given a small number of examples of scene-utterance pairs of a novel word, a child can determine both the range of syntactic constructions the novel word can appear in and inductively generalize to other scene instances likely to be covered by the concept represented (Pinker 1989). The inherent semantic, syntactic, and referential uncertainty in a single scene-utterance pair is well-established (c.f. Siskind 1996). In contrast, with multiple scene-utterance pairs, language learners can reduce the uncertainty of which semantic features and syntactic features are associated with a novel word.

Verbs exemplify the core problems of scene-utterance referential uncertainty. Verbs selectively participate in different alternation patterns, which are cues to their inherent semantic and syntactic features (Levin 1993). How are these features of words acquired, given only positive evidence of scene-utterance pairs?

The *syntactic bootstrapping* hypothesis (Gleitman 1990) is that learners exploit the distribution of “syntactic frames” to constrain possible semantic features of verbs. If a learner hears /glip/ in frames of the form /S glipped G with F/ and rarely hears /S glipped F into G/, the learner can with high confidence infer /glip/ to be in the same verb class as

/fill/ and have the same sort of argument structure. A different distribution informs the learner of a different verb class. Considerable evidence has mounted in support of this hypothesis (c.f. Naigles 1990, Fisher et al 1994). In contrast, the *semantic bootstrapping* hypothesis (Pinker 1989) is that learners use what is common across scenes to constrain the possible word argument structures. If a learner sees a liquid undergoing a location change when /S glipped F/ is uttered, then /glip/ is likely to be in the same verb class as /pour/ and have the same sort of meaning.

Both hypotheses require the distribution of cross-situational observations. Prior accounts to model word learning have either ignored the essential role of syntax in word learning (Siskind 1996, Tenenbaum and Xu 2000), or require thousands of training observations (Regier et al 2001) to enable learning. In this paper we present a Bayesian model of learning the syntax and semantics of verbs that overcomes these barriers, by demonstrating how word-concept mappings can be achieved from very little evidence, where the evidence is information from both scenes and syntax.

Bayesian Learning of Features

We illustrate our approach with a Bayesian analysis of a single feature. On some accounts, verbs possess a *cause* feature which may be valued 1, *, or 0 (Harley and Noyer 2000); depending on the value of the *cause* feature, the verb may appear in frame F1, F0, or both:

1	Externally caused - Ex: touch, load
F1:	He touched the glass.
F0:	*The glass touched.
*	Externally causable - Ex: break, fill
F1:	He broke the glass.
F0:	The glass broke.
0	Internally caused - Ex: laugh, glow
F1:	*He laughed the children.
F0:	The children laughed.

Assuming this analysis, learners who hear utterances containing a novel verb, not knowing the value of its *cause* feature, must choose between 3 distinct hypotheses H_1 , H_* , and H_0 . Clearly, one utterance cannot uniquely determine the value of the feature: if learners hear F1 (/S Ved O/), the feature sup-

ports H_1 or H_* ; similarly, if learners hear F0 (/O Ved/), the feature may be H_0 or H_* . Two utterances cannot determine the feature uniquely either. Learners might receive both F1 and F0, supporting H_* uniquely. But they may also accidentally receive 2 utterances of the same form (F0, F0 or F1, F1), thus not resolving the ambiguity. If learners received 6 utterances of the same form F0 or F1, however, then there is overwhelming support for H_0 or H_1 respectively, and H_* seems far less likely.

A Bayesian analysis renders the above analysis precise and quantitative. Knowledge is encoded in three core components: (1) the structure of the hypothesis space \mathcal{H} ; (2) the prior probability $p(H_i)$ on each hypothesis H_i in \mathcal{H} , before learners are provided any evidence; (3) the likelihood of observing evidence X given a particular H_i , $p(X|H_i)$. Given evidence $X = [x_1, \dots, x_N]$ of N independent observations, by Bayes' rule the posterior probability of a particular hypothesis H_i is:

$$p(H_i|X) = \frac{\prod_{j=1}^N p(x_j|H_i)p(H_i)}{p(x_1, \dots, x_N)} \quad (1)$$

signaling the support for a particular hypothesis H_i given evidence X .

In this case, x_j is the observation of a syntactic frame (F0 or F1), and X is a distribution of syntactic frames. One simple prior probability model $p(H_i)$ has each of the 3 hypotheses are equally likely, encoding that a verb is equally likely to be of the /touch/, /laugh/ or /break/ class:

$$p(H_1) = p(H_*) = p(H_0) = \frac{1}{3} \quad (2)$$

and a likelihood model $p(x_j|H_i)$ encoding how likely we are to observe frames F0 or F1 for the 3 different feature values of *cause*:

$$\begin{aligned} p(x_j = F1|H_1) &= .95 & p(x_j = F0|H_1) &= .05 \\ p(x_j = F1|H_*) &= .50 & p(x_j = F0|H_*) &= .50 \\ p(x_j = F1|H_0) &= .05 & p(x_j = F0|H_0) &= .95 \end{aligned} \quad (3)$$

The above likelihood model says that when a verb has *cause*=1, we expect frames of the form /S Ved O/ 95% of the time; when a verb has *cause*=0, we expect /O Ved/ 95% of the time; when a verb has *cause*=*, we expect both syntactic frames.

Both the prior probability model and likelihood model are *stipulated*, encoding a learner's prior knowledge of grammar. Given these probability models, this allows for explicit computation of the support of each hypothesis. Suppose a learner receives F0. Then the support for each of the 3 hypotheses may be computed to be:

$$\begin{aligned} p(H_1|F0) &= \frac{(.05)(.33)}{(.05 + .50 + .95)(.33)} = .033 \\ p(H_*|F0) &= \frac{(.50)(.33)}{(.05 + .50 + .95)(.33)} = .333 \\ p(H_0|F0) &= \frac{(.95)(.33)}{(.05 + .50 + .95)(.33)} = .633 \end{aligned} \quad (4)$$

Any number of situations may be analyzed as such:

Evidence X	$p(H_1 X)$	$p(H_* X)$	$p(H_0 X)$
1 F0	.033	.333	.633
2 F0, F0	.002	.216	.781
3 F0, F0, F0, F0, F0, F0	2e-8	.021	.979
4 F0, F1	.137	.724	.137
5 F0, F1, F0, F1, F0, F1	.007	.986	.007
6 F0, F1, F1, F1, F1, F1	.712	.288	5e-6

When only F0 is given as evidence (situation 1), while both H_0 and H_* are consistent with the observation, H_0 is nearly twice as likely. However, with 2 observations of F0 (situation 2) or 6 observations (situation 3), it is increasingly likely that H_0 is the correct hypothesis. With both F0 and F1 as evidence (situation 4), in contrast, H_* is far more likely; with more evidence (situation 5), it becomes more so. Finally, if the first frame is a "noise" frame and followed by 5 representative frames of F1 (situation 6), then H_1 is more likely instead.

Given this framework, just one or two observations is sufficient to make an informed judgement. Note that each additional observation increases certainty, and noise is handled gracefully.

Modeling Semantic Bootstrapping

In this section, we extend the single feature analysis to multiple features, where each feature represents information from scenes (from any modality, whether perceptual, mental, etc.). Setting aside verbal aspect, we may model possible verb meanings as a set of M features, where each feature represents a predicate on one or more of the arguments of the verb. For example, a set of single argument predicates might include:

moving(x), rotating(x), movingdown(x),
supported(x), liquid(x), container(x)

specifying the perceived situation about the argument of the verb (e.g. if it is moving, or moving in a particular manner, etc.) while a second set of two-argument predicates might specify the relationships between arguments, given that this is an externally caused (*cause*=1) event:

contact(x, y), support(x, y), attach(x, y)

Using these predicates, an idealized (partial) lexicon might contain the following word-concept mappings:

	<i>cause</i>	One arg x	Two arg x, y
/lower/	1	1*11**	11*
/raise/	1	1*01**	11*
/rise/	0	1*0***	
/fall/	0	1*1***	

specifying, in linear order, the value of each of the one and two-argument predicates above, e.g. that /lower/ has *cause*=1, moving(x)=1, rotate(x)=*, movingdown(x)=1, etc. - and thus its concept covers externally-caused motion events where an agent moves a theme downwards through supported contact. The verb /raise/ is nearly identical except it has movingdown(x)=0, while /fall/ and /rise/ involve internally-caused motion (*cause*=0) and do not

specify any two argument predicates. The values of * for the 4 rotating(x), liquid(x), container(x), and attach(x,y) predicates signal that these features are irrelevant to the verb's concept. Perception of a scene amounts to evaluating these predicates; scenes may or may not fall under the verb concept, conditioned on the values of these predicates. The presence of q of "irrelevant" features valued as * implies 2^q possible scenes consistent with the concept.

Given a hypothesis space of possible verb concepts formed by M of these sorts of predicates, the task of learning a verb's meaning given N observations $X = [x_1 \dots x_N]$ of scenes, is to determine which of the 3^M possible concepts is the most likely. Just as before, a Bayesian model does so by computing the posterior probability distribution $p(H_i|X)$ over concepts, given a prior distribution on hypotheses $p(H_i)$ and a likelihood distribution of generating a particular x_j example given H_i :

$$p(x_j|H_i) = \begin{cases} \frac{1}{2^q} & \text{if } x_j \in H_i \\ 0 & \text{otherwise} \end{cases}; p(H_i) = \frac{1}{3^M} \quad (5)$$

We can use Bayes' rule (Eq (1)) to compute the likelihood of any hypothesis given N independent examples. Intuitively, the above likelihood model says that out of the 2^q possible scenes that might fall under the concept H_i , all of them are equally likely; likewise, the prior probability model holds that all of the 3^M concepts are equally likely.

Consider a reduced hypothesis space where $M = 3$:

q	Concepts
0	000, 001, 010, 011, 100, 101, 110, 111
1	00*, 01*, 10*, 11*, 0*0, 0*1, 1*0, 1*1, *00, *01, *10, *11
2	0**, *0*, **0, 1**, *1*, **1
3	***

Given any distribution of scenes X , we can directly compute the posterior probability $p(H_i|X)$ of any of the 27 different concepts. Four are shown here, of increasing generality from a very specific concept (H_{000}) covering only one scene (000) to the most general concept H_{***} covering 2^M possible scenes:

Observation X:	H_{000}	H_{00*}	H_{0**}	H_{***}
1 000	.30	.15	.07	.03
2 000, 000, 000	.70	.09	.01	.001
3 000, 001	.00	.64	.16	.04
4 000, 001, 000	.00	.79	.10	.01
5 000, 001, 000, 001, 000	.00	.94	.03	.001
6 000, 101, 010, 111, 000	.00	.00	.00	1.0

A single scene observation 000 is explained by all 4 hypotheses (situation 1) in a graded fashion. However, with 3 repeated observations (situation 2), most of the mass is concentrated on H_{000} . When scene observations require abstracting away irrelevant features, the more specific concepts must be discarded in favor of more general concepts (situation 3 vs 6). Each example consistent with the general concept further reduces ambiguity over the possible concepts (situation 4 vs 5).

Modeling Syntactic Bootstrapping

In this section, we demonstrate a Bayesian model of how the distribution of syntactic frames, as envisioned by Gleitman (1990), may be used to determine the semantic features of a verb. To do so, we introduce a new notion of *semantic agreement*, wherein features of a lexical head must agree with its complement. Consider the following idealized lexicon:

/fill/	fig: [0]	con: [1]	/into/	fig: [1]
/pour/	fig: [1]	liq: [1]	/with/	fig: [0]
/load/	fig: [*]		/glass/	con: [1]
			/water/	liq: [1]

A lexical head /fill/ agrees with a complement of /a glass with water/ but not with /water into a glass/, because the lexical head and its complement have a value 1 along the *fig* dimension. Likewise, a lexical head /pour/ agrees with a complement of /water into a glass/ but not /a glass with water/, because of the opposite value of *fig*. Finally, a lexical head such as /load/, because * agrees with 0 and 1, accepts both complements. Thus, both /load the wagon with hay/ and /load hay into the wagon/ are valid derivations. A large number of verb classes can be seen to pattern into three classes along different feature dimensions in this way (Nomura et al 1994).

Any number of feature dimensions may be hypothesized, and may include selectional features, such as /fill/ requiring a container (con:[1]) or /pour/ requiring a liquid (liq:[1]) as its complement.

Suppose a learner hears /S glipped a glass with water/. The features of the novel verb /glip/ are unknown and the features of its complement /a glass with water/ are known. For the *fig* feature dimension of /glip/, there are 3 possible values, with 3 corresponding hypotheses H_0, H_1, H_* . As before, one observation is insufficient to infer H_0 , as H_* is also possible. The following likelihood model for an unknown verb feature value V and the feature value of its complement C agreeing can be used for each feature dimension (*fig*, *loc*, *con*, etc.) to compute a probability distribution over the H_i :

$p(V, C)$	$V = 0$	$V = 1$	$V = *$
$C = 0$.22	.01	.11
$C = 1$.01	.22	.11
$C = -$.11	.11	.12

Intuitively, the above says that with high probability, V and C agree, and with low probability (i.e. .01), they do not agree. The above joint distribution encodes both the prior distribution on V and the conditional distribution $p(C|V)$:

$$p(V = 0) = p(V = 1) = p(V = *) = \frac{1}{3} \quad (6)$$

$$\begin{aligned} p(C = V|V = 0 \text{ or } 1) &= .65 \\ p(C \neq V|V = 0 \text{ or } 1) &= .03 \\ p(C = *|V = 0 \text{ or } 1) &= .32 \end{aligned} \quad \begin{aligned} p(C = 0, 1|V = *) &= .32 \\ p(C = *|V = *) &= .35 \end{aligned} \quad (7)$$

Given an assumption of perfect knowledge of the feature values of the complement, over multiple observations, the distributional evidence X in support of the 3 hypotheses can be readily evaluated. We can test how different distributions of syntactic frames correctly yield different probability distributions of a verbs syntactic and semantic features; this is thus a Bayesian model of Gleitman's (1990) "syntactic bootstrapping". Suppose a learner gets 4 syntactic frames of /glip/, all of the form /S glipped O with Z/. This is equivalent to having 4 perfect observations of fig:[0], which we annotate as $X = 0000$. Then the likelihood $p(X|V)$ and posterior probability $p(V|X)$ of the 3 possible hypotheses can be evaluated directly via Bayes' rule:

Likelihood $p(X V)$	Posterior $p(V X)$
$p(X V=0) = (.65)^4$	$p(V=0 X) = .941$
$p(X V=1) = (.03)^4$	$p(V=1 X) = .000$
$p(X V=*) = (.32)^4$	$p(V=* X) = .059$

This is shown below, along with other distributions of syntactic frames:

Sit	Utterances (X)	V=0	V=1	V=*
1	4 /S Ved O with Z/ (0000)	.941	.000	.059
2	4 /S Ved O/ (****)	.292	.292	.416
3	2 /S Ved O with Z/, 2 /S Ved O into Z/ (0011)	.032	.032	.936
4	2 /S Ved O/, 2 /S Ved O with Z/ (**00)	.769	.000	.230
5	23 /S Ved O with Z/ 10 /S Ved O/	1.00	.000	.000
6	5 /S Ved O into Z/ 10 /S Ved O/	.960	.000	.040

With only 4 examples, the uncertainty of the value of the feature V is rapidly reduced (situations 1-4). As the number of examples increases (situation 4 vs 5), the evidence supports "all-or-none" or "rule-like" behavior, even with a significant number noisy frames (situation 5 vs 6).

Modeling Integrated Syntactic and Semantic Bootstrapping

We now integrate the two forms of bootstrapping described above, where given a distribution of both scenes and syntactic frames, a probability distribution over concepts consistent with both sources of evidence is determined. Consider the following possible syntactic frames:

Utterance	u	Attention
/Glipping/	***	-
/S glipped water from a glass/	1**	W
/S glipped water into a glass/	1**	W
/S glipped water/	***	W
/S glipped a glass with water/	0**	G
/S glipped a glass/	***	G

and perceptually-derived semantic features of scenes:

Scene s	Description/Semantic Features
pour-fill	Person pouring water into a glass, filling it
G ₀₀₁	Glass: Manner: None (0) State: Full (1)
W ₁₁₀	Water: Manner: Pouring (1) State: None (0)
splash-fill	Person splashes water into a glass, filling it
G ₀₀₁	Glass: Manner: None (0) State: Full (1)
W ₁₂₀	Water: Manner: Splashing (2) State: None (0)
spray-fill	Person sprays water into a glass, filling it
G ₀₀₁	Manner: None (0) State: Full (1)
W ₁₃₀	Manner: Spraying (3) State: None (0)
pour-empty	Person pouring water out of glass, emptying it
G ₀₀₂	Manner: None (0) State: Empty (2)
W ₁₁₀	Manner: Pouring (1) State: None (0)
splash-empty	Person splashes water out of glass, emptying it
G ₀₀₂	Manner: None (0) State: Empty (2)
W ₁₂₀	Manner: Splashing (2) State: None (0)
pour-none	Person pouring some water into a glass
G ₀₀₀	Manner: None (0) State: None (0)
W ₁₁₀	Manner: Pouring (1) State: None (0)
spray-none	Person sprays water into a glass
G ₀₀₀	Manner: None (0) State: None (0)
W ₁₃₀	Manner: Spraying (3) State: None (0)

where features are ordered as:

fig, manner-of-motion, change-of-state

for each utterance u and scene possibility s . The subscripts on G and W annotate the observation of that argument for each of the 3 dimensions.

We may describe, just as before, how the cross-situational distributional evidence X of N independent scene-utterance pairs:

$$X = [(s_1, u_1), \dots, (s_N, u_N)] \quad (8)$$

yields different word-concept mappings $p(H_i|X)$ through independent combination of the two sources of evidence:

$$p(H_i|X) = \frac{\prod_{j=1}^N p(s_j|H_i)p(u_j|H_i)p(H_i)}{p(X)} \quad (9)$$

For expository purposes, we will consider how the learner would rank each of the 6 precise hypotheses, and will assume they entertain only these:

English Verb	Hypothesis	Feature
pour	H_{pour}	11*
spray	H_{spray}	12*
splash	H_{splash}	13*
fill	H_{fill}	0*1
empty	H_{empty}	0*2
move	H_{move}	1**

The likelihood $p(s_j|H_i)$ for each of the D independent dimensions ($D = 3$) is:

$$p(s_j = s_1 \dots s_D | H_i) = \prod_{k=1}^D p(s_k | H_i) \quad (10)$$

where our model for scene observations along the k th dimension is:

$$p(s_k | H_i) = \begin{cases} 1 - d_k \epsilon & \text{if } s_k = 0, H_i^k = * \\ \epsilon & \text{if } s_k \neq 0, H_i^k = * \\ 1 - d_k \delta & \text{if } s_k = H_i^k, H_i^k \neq * \\ \delta & \text{if } s_k \neq H_i^k, H_i^k \neq * \end{cases} \quad (11)$$

We annotate the value of the k th dimension of hypothesis H_i as H_i^k above. The first two lines model that when a feature is not valued ($H_i^k = *$), then scenes typically have 0 for the k th dimension ($d_1 = 2; d_2 = 3; d_3 = 3$), but do not match with probability ϵ . That is, observing pouring, spraying, splashing manners ($s_2 = 1, 2$, or 3), and observing filling, emptying, or breaking change-of-states ($s_3 = 1, 2$, or 3)

Situation	Scene s	Utterance u		H_{pour}	H_{spray}	H_{splash}	H_{fill}	H_{empty}	H_{move}
1	pour-fill	G_{001}, W_{110}	/S glipped water into a glass/ (1**)	.889	.008	.008	.000	.000	.093
2	pour-fill	G_{001}, W_{110}	/S glipped glass with water/ (0**)	.000	.000	.000	.990	.009	.000
3	pour-fill	G_{001}, W_{110}	/Glipping!/ (***)	.468	.004	.004	.468	.004	.049
4	none		/S glipped water into a glass/ (1**)	.246	.246	.246	.004	.004	.254
5	none		/S glipped glass with water/ (0**)	.007	.007	.007	.485	.485	.007
6	none		/Glipping!/ (***)	.166	.166	.166	.166	.166	.170
7	pour-fill	G_{001}, W_{110}	/Glipping!/ (***)	.998	.000	.000	.000	.000	.001
	pour-empty	G_{002}, W_{110}	/S glipped water from a glass/ (1**)	.998	.000	.000	.000	.000	.001
	pour-none	G_{000}, W_{110}	/S glipped water/ (***)	.998	.000	.000	.000	.000	.001
8	pour-fill	G_{001}, W_{110}	/Glipping!/ (***)	.000	.000	.000	.999	.000	.000
	splash-fill	G_{001}, W_{120}	/S glipped a glass with water/ (0**)	.000	.000	.000	.999	.000	.000
	spray-fill	G_{001}, W_{100}	/S glipped a glass/ (***)	.000	.000	.000	.999	.000	.000
9	pour-fill	G_{001}, W_{110}	/Glipping!/ (***)	.064	.064	.064	.000	.000	.808
	splash-empty	G_{001}, W_{120}	/S glipped water/ (***)	.064	.064	.064	.000	.000	.808
	spray-none	G_{001}, W_{100}	/S glipped water/ (***)	.064	.064	.064	.000	.000	.808

Figure 1: Word-concept mapping $p(H_i|X)$, given scene-utterance evidence X of a novel verb, /glip/

is far less likely than observing no manner of motion ($s_2 = 0$) or change of state ($s_3 = 0$) at all. Since observing a different value $s_j \neq 0$ is unlikely to have occurred by accident, it may be an important feature to the concept. The second two lines of (11) model that if a feature is valued ($H_i^k \neq *$), then scenes typically match that feature in value, but do not match with probability δ . That is, for example, given hypothesis H_{pour} , then most of the scenes will contain pouring in them. In our examples, $\epsilon = .1, \delta = .01$; qualitatively, results are not sensitive to changes in these values.

The output of our model is shown in Figure 1.

Suppose, as in Situation 1, a learner is given a single scene-utterance pair (pour-fill, /S glipped water into the glass/): $X = [(s_1 = \{G_{110}, W_{110}\}, u_1 = 1**, W)]$, and we wish to compute $p(H_i|X)$ for all $H_i \in \mathcal{H}$. We assume the learner can attend to the argument so as to extract relevant features from the scene. Given the scene pour-fill paired with utterance /S glipped water into a glass/, our Bayesian model places high weight on H_{pour} .

In Situation 2, the scene is the same, but now the syntax /S glipped a glass with water/ provides the learner with the information to attend not to the water's manner-of-motion but to the glass' change of state. Given $X = [(s_1 = \{G_{110}, W_{110}\}, u_1 = 0**, G)]$ our model weights H_{fill} heavily.

In Situation 3, the scene is the same, but now the syntax /Glipping!/ gives the learner less information, since the argument in the scene that the speaker may be referring to is unknown: $X = [(s_1 = \{G_{110}, W_{110}\}, u_1 = - - -)]$ If there are A arguments in the scene, the speaker must have had a particular argument z in mind. The learner must condition on all the possibilities of z :

$$p(s_j|H_i) = \sum_{a=1}^A p(s_j|H_i, z_a)p(z_a) \quad (12)$$

If learners consider all arguments equally salient ($p(z_i) = \frac{1}{A}$) then this effectively models /Glipping!/

as equivalent to /S is glipping Z1/ with probability $p(z_1) = .5$ and /S is glipping Z2/ with probability $p(z_2) = .5$. For simplicity, we assume $A = 2$ where Z1 is water, Z2 is the glass – but further referential uncertainty can be modeled with higher A . Because of the conditioning on each of A possibilities, this yields a less certain word-concept mapping.

In situation 4 through 6, the same syntactic frames are provided as in situations 1 through 3, but without the scene information. When some syntactic information is provided by the frame (situation 4, /S is glipping water into a glass/), then the manner-of-motion locative verbs are preferred over the change-of-state locative verbs, but no differentiation is possible without the scenes. Likewise, when the frame provides the opposite cue (situation 5, /S is glipping a glass with water/), the opposite preference is achieved, again with no differentiation between possible change-of-state verb concepts. When zero syntactic information is available (situation 6, /Glipping!/), all hypotheses prove equally likely.

Whereas in situation 3 the verb-concept mapping was ambiguous, primarily between H_{pour} and H_{fill} , in situation 7 and 8, learners are provided 2 additional examples to disambiguate. Both the scenes and syntactic frames in situation 7 support H_{pour} , while in situation 8 the scenes and syntactic frames support H_{fill} .

Finally, in situation 9, 2 different scene-utterance pairs primarily support the “superordinate” concept H_{move} , and not any “subordinate” manner-of-motion concept H_{pour} , H_{splash} , or H_{spray} .

Discussion

The reason why our analysis is able to infer so much from so little evidence is because so much is embedded in the given knowledge sources:

- the structure of the hypothesis space \mathcal{H} . Our examples contained a small number of feature dimensions and their possible values, but these may

be specified by interfaces to perceptual, motor, memory, or other “theory” representations. If so, whether these are innate or acquired are conditional on their source.

- priors $p(H_i)$ on hypotheses in \mathcal{H} . We used equal priors, but updating $p(H_i)$ based on language input is natural. In the verbal domain, such phenomena are commonly observed (e.g. manner vs. path, tight/loose-fit biases).
- likelihood of scenes s given the word concept $p(s_j|H_i)$. We stipulated static values of ϵ and δ , but this can be acquired from observation.
- perfect knowledge of the features of the complement. We made this simplifying assumption to illustrate the essential elements of our model, but learners must acquire these features in parallel.
- the likelihood of agreement, $p(C|V)$, between a feature of a novel verb V and its complement C . We speculate that there is sufficient structure in partially learned words so as to acquire the structure in the joint distribution of feature values.

This richness of knowledge is in contrast to the models employed by Regier et al (2001) and Desai (2001), who train connectionist neural networks so as to learn the word-scene associations for adjectives/ nouns and verbs respectively. The high dimensionality of their models forces the need for thousands of training trials, and the interpretation of the weights is notoriously difficult. The assumptions behind these models are not justified by these authors. In contrast, our Bayesian approach makes the hypotheses, priors, and likelihoods explicit, holding this structure to be central.

Siskind (1996) views lexical acquisition as constraint satisfaction, and offers a robust algorithm where the mapping between input and hypothesis space is accomplished by pruning hypotheses that do not occur cross-situationally. Provided an idealized tokenization of the world, the algorithm does not need a large number of examples. However, Siskind’s model does not yield any form of preference between different concepts, which is especially important when two or more concepts may be equally constrained by the data. We have shown how a Bayesian analysis explicitly yields preferences between concepts in the posterior probability distribution $p(H_i|X)$.

Tenenbaum and Xu (2000) take the important step of putting word learning in the Bayesian framework that we adopt here, showing how noun learning can occur with a small number of examples in a continuous-variable input space.

Crucially, however, the above models ignore the constraining role of syntax, despite considerable evidence that children use syntax to guide their verb-concept hypothesis space (Gleitman 1990, Naigles 1990, Naigles 1994, Fisher et al 1994, Snedeker and

Gleitman 2002). Qualitatively, our models’ performance matches the preferences of child learners, modeling their acquisition from as little as one example.

Our use of statistics does not imply any commitment to radical empiricism. Much prior knowledge is stipulated: the structure of the hypothesis space, the priors on hypotheses, and the likelihood of scene-utterance pairs given the hypotheses. It is not specified whether these stipulations are innate or themselves learnable. Linguistics and lexical semantics provide detailed theories of a much larger syntactic and semantic hypothesis space, and little prevents their inclusion in this framework.

Abstract

Evolutionary systems are conceptualized as having four transfer functions between the two state spaces of genotype and phenotype. The four transfer functions are epigenesis, survival, mate selection, and genetic recombination. The treatment of these transfer functions is uneven at best. In particular, some complain that epigenesis, the formation of an entity from the original undifferentiated cell mass into tissues, is treated in a too simplistic manner to allow for system flexibility, or creativity. This paper reports on an interactive image evolving system that mimics the morphogenesis processes in epigenesis. System description, results, and theoretical implications are discussed.

Introduction

Interactive evolutionary systems seek to interface evolutionary programming to human preference in order to create systems capable of evolving artifacts that require a human expertise that hasn't yet succumb to computation. A common area for this endeavor is the evolving of art, particularly image. The interfacing of human ability with machine computation requires resolving difficult issues in the arts, humanities, and sciences. Further, progress in the design of interactive evolutionary systems allows a glimpse into how very human abilities such as intuition, projection, and holistic perception interplay with the mechanics of machine computation. This paper reports on one such interactive evolutionary system that seeks to combine human perception with the genetic algorithm to evolve small holistic images.

Humans lack the tremendous numerical computational speed of computers; yet they can process information holistically in an automatic, rapid, and natural manner. Machines possess tremendous computational capabilities; yet no algorithm exists to perform holistic processes as well as humans do. Ideally, a good interactive system would integrate the best human cognitive qualities with machine computational capabilities enabling the resultant hybrid system to outperform either of the two components alone. Evolutionary computation as an algorithm is well suited for the creation of an interactive imaging system. However, problems exist in implementation: How can evolutionary computation best support the holistic processes of human cognition? To answer this question requires an

understanding of current theory regarding human holistic processes.

Psychological Issues

A well-known area in cognitive research that studies holistic processes is the recognition of objects and, in particular, the recognition of faces. Different perceptual encoding and representational processes have traditionally differentiated theories regarding the recognition of objects as compared to faces. However, the functional separation of these processes under all conditions of object recognition remains unclear (Bruce & Humphreys, 1994). Much of basic object recognition theory has been based on the decomposition of parts and the analysis of edge features (Marr & Nishihara, 1978; Biederman, 1987; Ullman, 1989). On the other hand, face recognition theory has been based on more holistic processes which utilize surface characteristics such as texture, color, and shading (Price & Humphreys, 1989). Some research suggests that the distinctions between object and face recognition begin to fade when one examines the object recognition processes of experts, who may utilize holistic processes similar to those found in face recognition (Diamond & Carey, 1986; Rhodes & McLean, 1990).

The theory regarding holistic processing of faces can be separated into stronger and weaker stances (Bruce & Humphreys, 1994). Under the weaker stance, features may interact with each other through configurational processes to form emergent properties or "second-order relational features" (Diamond & Carey, 1986). Under the stronger stance, face recognition is completely holistic; that is, its representation is non-decomposable in that no explicit description of features exists outside the context of the face (Tanaka & Farah, 1993). These stances provide two ways of approaching the development of an interactive system to support the holistic development of images: (1) A system which manipulates context-free features towards configuration, or (2) a system which develops the configuration of the image first, followed by more detailed development of features within the established context.

We sought to design a recognition-driven system of the latter type, which would support the purely holistic development of images, including faces and objects. This system would function in a feature-free space to provide a

non-decomposable representation of images. For instance, a human may perceive or project a cloud as containing the image of a face, yet a cloud contains no explicit representation of the eyes, nose, or mouth. Such features, say a nose, would only be perceived as a nose within the context of the cloud's facial image. This type of perception or projection of a natural texture is called *objet trouvé*, and is thought by some (Gombrich, 1960) to be paramount to the perception of art. Further, a cloud is not limited to faces; it might contain other animals, or objects. The cloud merely contains randomly distributed textures which humans can organize perceptually. Just as a cloud supports holistic recognition of images, an interactive evolutionary system could encourage recognition based upon context-dependent rather than context-free properties. We intended to provide a mechanism by which a cloud-like representation could enter into "cumulative selection", in a manner not unlike the wishful thinking of Dawkins (1987).

System Issues

The system presented in this paper can be distinguished from other work in the interactive evolution of images (Dawkins, 1987; Baker & Seltzer, 1994; Sims, 1991; Caldwell & Johnston, 1991; Johnston & Caldwell, 1997; Todd & Latham, 1992). Many interactive evolutionary systems (Dawkins, 1987; Baker & Seltzer, 1994; Sims, 1991; Todd & Latham, 1992) use aesthetic preference to determine the fitness of images that are composed of context-free features. Under conditions of aesthetic preference, the user evolves images opportunistically. These systems do not easily support evolution towards an *a priori* goal. Baker and Seltzer (1994) opportunistically evolved butterflies from randomly generated lines, but when they intentionally evolved a general "face-like" image, they could do so only with difficulty. Further, previous systems sometimes required input images to enable the evolution of faces. Sims (1991) as well as Baker and Seltzer (1994) modified facial images after providing input images of human faces, and Johnston and Caldwell (Caldwell & Johnston, 1991; Johnston & Caldwell, 1997) provided input images of features to evolve configured faces.

The Johnston and Caldwell system (Caldwell & Johnston, 1991; Johnston & Caldwell, 1997) is most similar in purpose to our system in that they used human recognition to evolve images of criminal suspects. Their "Faceprints" system allowed more goal-directed behavior within interactive evolution than previously achieved, and they developed a system that encouraged holistic processes by presenting configured faces from the start. However, their system differs from ours in that they took the weaker theoretical stance towards holistic processing by providing input images of context-free features and then placing them in a randomly generated configuration for further evolution.

The "Faceprints" system represents an approach which is common to evolutionary computation; that is, the majority

of evolutionary computation is based on parameterized models which predefine features and pre-encode dimensions upon which the features can vary. A key component of evolutionary computation is the mapping between the genotype and phenotype representations. The genotype representation consists of a string of characters, usually binary, that are used as genetic codes in the reproductive process. The phenotype representation consists of a description of an organism that can be evaluated for fitness and selected for reproduction. The linkage between the genotype and phenotype representations is accomplished by a mathematical mapping that uses a parameterized model. For instance, to evolve rectangles, one could create a formula with the two parameters of height and width that would scale suitable binary numbers to a rectangle of a certain height and width. The binary numbers would form the genotype, and the resultant rectangles would form the phenotype.

There are many problems associated with approaches based on a parameterized model (Hofstadter, 1982). The main problem for creating images is that parameterized models constrain the phenotype representation. A model for rectangles can never create a circle. We might try to escape the problem by adding a selector parameter that would dictate the geometric shape to use. For instance, in a rectangle model, if we wanted to represent circles also, we could add a selector parameter that would indicate whether to implement a rectangle model or a circle model. The repair works, except that the addition leads to a discrete selector parameter function and potentially requires an infinite number of models to represent all objects. Instead, we seek to create a system that avoids the predefinition of features and the mapping of genotype to phenotype.

Image Elicitation System

Instead of using a feature-based space, we created a frequency-based space based on pixel representation. The pixel space representation affects the resolution of the images, but forces no predefined features upon the images themselves. The space is based upon atomic or molecular representation, similar to the notions of atomic or molecular decomposition by Fourier analysis or wavelets (Meyer, 1993). As championed by the pointillists, small points of just a few colors can be used to create the psychological impression of any form and any color. Atomic representation works at the sub-feature level and allows the generation of features along with their configuration. The representation is not constrained by features and encodes a dog, a tree, or a car as easily as a face. For instance, one could create a pixel space of 25-by-25 pixels (625 total units) with each pixel being any of eight colors (three bits of information.) Such a small pixel space has the informational potential to create an enormous number of images, as many as 21875. The number of possible images is so large that there exists no real constraints on the variety

of forms that may be represented; rather, the model constrains the resolution of the image. In terms of resolution, the space cannot represent objects that require more than 12.5 lines of resolution (each line requires at least one 'on' and one 'off' pixel) in the vertical or horizontal axis. However, increasing the number of pixels and decreasing the pixels' size can reduce the impact of the constraint.

System implementation required addressing additional issues in the method of reproduction and mutation function. First, usually, simple cross-over points are used as the method of reproduction, but such a linear system is inappropriate for a two-dimensional space. Instead, we increased the number of cross-over points until the reproductive system considered a cross-over point at every allele. Such a system of uniform crossovers was implemented by randomly selecting between the genes of the two parents with equal probability. Although some researchers consider uniform crossovers to be deleterious to evolutionary computation (Fogel, 1995), others have found them to be useful (Syswerda, 1989). Secondly, if one uses a mutation function that chooses among all possible genes with equal probability for an allele, the mutation function will eventually return the image to a random state. Instead, we limited the mutation function to the gene values of neighboring pixels, causing smaller changes and greater adaptability.

Each generation has a population of fifty images of which the human selects ten images for use as the parents for the next generation. The resulting image elicitation system consists of a comma plus system since the parents are available for selection in the next generation so that each generation after the first is made of parents plus their offspring (Heitköttere & Beasley, 2002). The genotype representation is an array of alleles that has the same size as the pixel representation (25x25 pixels). Each allele is a character that corresponds to one of the possible colors (or genes) for the pixel. Reproduction creates the offspring genotype by randomly and uniformly selecting between the genes of two randomly selected parents at each allele site.

Results

For purposes of this paper, and given our emphasis on holistic processes, we chose a face as the image to be elicited. The first author began with the specific goal of "elicit Abraham Lincoln" and elicited an image of Abraham Lincoln using four levels of gray (figure 1). The image represents the results of image elicitation after 245 generations. The image was originally generated on a SVGA monitor using a black background. A human's ability to recognize Abraham Lincoln is very dependent on the spatial frequency of the image. In other words, viewing figure 1 at too close or too far of a distance reduces the perceptual quality of the image. Figure 2 displays the evolution of the stochastic prototype of Abraham Lincoln.

The matrix represents every fifth generation of Abraham Lincoln's image up to generation 245. The matrix should be scanned from left to right and from top to bottom. Each image is a stochastic prototype created by randomly selecting and copying a gene from one of the ten parents into the corresponding allele of the prototype until each allele of the prototype is created. The sampling function is a uniform, random distribution over the parents. As a result, the composite prototype is similar to all of its parents and evokes the average recognition of its parents.

Theoretical Impact

The process in image elicitation is best described in terms of co-evolution or holistic evolution. This description runs contrary to mainstream thought on how evolutionary computation works. There are currently two ideas on how convergence happens in evolutionary computation: the Building Block Hypothesis by Goldberg (1989) and the Schema Theorem by Holland (1992). We argue that both of the hypotheses are feature analytic and are insufficient to explain what is happening in image elicitation.

The Building Block Hypothesis suggests that the convergence process in evolutionary computation is based upon building blocks or small groups of characters whose introduction into any genotype representation will likely increase the fitness of the phenotype representation. Goldberg suggests that the genetic computation first finds as many of these building blocks as possible, and later in evolution, the building blocks are combined together to give the highest fitness. For instance, a series of 1's in the genotype might give rise to an eyebrow in the image. The presence of an eyebrow in any picture of a face should increase the image quality, and, therefore, the fitness.

The Schema Theorem suggests that the ongoing process in evolutionary computation is implicit parallelism caused by schema processing. Schemata are defined as patterns of characters in the genotype representation that may include "don't care" states. A schema can be specified by a genotype representation in which each gene contains a 1 for "on", 0 for "off", or X for "don't care". In a sense, a schema is a relaxed building block in that it relaxes how tightly clustered the group of "care" genes are. Each genotype representation can contain a large number of schemata. This leads to the implicit parallelism and speeds up search.

The basis for our criticism of the current theories lies in their assumption that one can analyze the genotype while disregarding the phenotype. It also requires one to accept that all intermediate representations (patterns in the genotype that are tried and not kept) are coincidental to the process. In such a view one need only look back from the evolved solution and trace the heritage of its genes. In both theories, the implied process is analytical.

Image elicitation challenges these theories in terms of process and representation. Image elicitation relies on multiple-gene (holistic) representation as opposed to

variable-encoded (feature-based) representation. In image elicitation, the image exists in the phenotype and in the perception of the observer, whereas, in other evolutionary computation, the image description exists in the genotype. Our system allows polygeny and pleiotropy, whereas current theory is based on a direct mapping from the genotype to the phenotype and no separate mapping backwards from the phenotype to the genotype. We can illustrate our theoretical differences through what we call "the gray argument" for holistic processes.

Consider the evolution of a medium gray. Mapping from the gray phenotype back to the genotype reveals two optimal representations as shown by *a* and *b* in figure 3. Using binary representation, where 1 equals an "on" pixel, 0 equals an "off" pixel, and X equals "don't care", one finds that 1010101... is one representation (*a*) and its complement 0101010... is the other (*b*). Strangely, one can breed together these complimentary representations and the offspring *c* and *d* will still appear grayish in the phenotype, regardless of genotype of the parents, or type of crossover function used. Grays *c* and *d* result from the use of simple and uniform crossover respectively. How can one describe the process of evolving grays in terms of building blocks or schemata when the phenotype being selected does not depend upon any particular gene being a 1 or 0 or X? The gray phenotype can only be described in the genotype as a fairly uniform distribution of 1's and 0's. Given that the difficulties in phenotype-to-genotype mapping of grays extend to all images, the Building Block Hypothesis and the Schemata Theorem are insufficient to describe an image's evolution. In fact, the gray argument is problematic for many current approaches used to understand, or represent phenotype-to-genotype mapping.

Conclusions

Image elicitation promotes wholeness or a lack of distinct features. If one observes the evolving of Lincoln's image one will notice that the features all co-evolve together. At no time does the process treat the nose differently from the eye. The process is so tightly interwoven that to distinguish the nose from the rest of the face constitutes a false distinction; the nose gets its description from itself and the context provided by the rest of the image.

Image elicitation affords high-order interactions. The placement, sizing, shading, and coloring of an image that bears strong resemblance to the original (e.g., a face) can only be described as highly interactive. The placement, size, etc. of the nose is dependent upon all the other features of the face, for if the nose is anywhere but the right place in relation to other features the image would have no resemblance. High-order interactions are a problem for analytical processes, but not this method. It evolves a complex stimulus within a large information space while

maintaining a small population size and a reasonable number of generations.

Image elicitation appears to promote holistic rather than analytical processes. It begins with the grossest of detail and ends with the finest of detail. The elicitation process uses intermediate approximations as placeholders for features and as a means of resolution building. This process of organizing an undifferentiated representation into finer and finer regions, or features appears to mimic the process of morphogenesis found in biological reproduction. We argue that features, which by their nature are fine detail and not available until the end of convergence, cannot be used to explain the process. Such findings are problematic for the building block and schemata theories that are currently used to explain the processes in evolutionary computation.

Summary

The present image elicitation system provides a new technique for integrating the best qualities of human and machine capabilities to create images. Neither system could produce these images alone. Machines lack the perceptual and memory skills, and humans lack the computational energy to evolve an image. The results show that current theories of evolutionary computation are insufficient to explain the convergence of the images in the absence of a feature-based parameterized space.

The technique of image elicitation allows humans to use their perceptual and cognitive systems to organize visual noise into the objects of their memories. This process of literally pulling an image out of chaos will affect our understanding of intelligent systems and future investigations across many disciplines. Image elicitation will be useful in studying machine intelligence, as well as in studying top-down processes in interactive intelligent systems. The system provides a means for humans to experience how evolutionary computation works by directly immersing themselves in the process. And, it provides cognitive researchers with a means of studying holism in human recognition.

Figures

Abstract

Student responses to conceptual physics questions were analyzed with latent semantic analysis (LSA), using different text corpora. Expert evaluations of student answers to questions were correlated with LSA metrics of the similarity between student responses and ideal answers. We compared the adequacy of several text corpora in LSA performance evaluation, including the inclusion of written incorrect reasoning and tangentially relevant historical information. The results revealed that there is no benefit in meticulously eliminating the wrong or irrelevant information that normally accompanies a textbook. Results are also reported on the impact of corpus size and the addition of information that is not topic relevant.

Introduction

AutoTutor is an intelligent tutoring agent that interacts with a student using natural language dialogue (Graesser, Person, Harter, & TRG, in press; Graesser, VanLehn, Rose, Jordan, & Harter, 2001). The tutor's interactions are not limited to single-word answers or formulaic yes/no decision trees. AutoTutor attempts to tackle the problem of understanding lengthy discourse contributions of the student, which are often ungrammatical and vague. AutoTutor responds to the student with discourse moves that are pedagogically appropriate. It is this cooperative, constructive, one-on-one dialogue that is believed to produce learning gains (Graesser, Person, & Magliano, 1995). One major component in the comprehension mechanism is the knowledge representation provided by Latent Semantic Analysis (LSA). LSA is a statistical, corpus-based natural language understanding technique that

computes similarity comparisons between a set of terms and texts (Kintsch, 1998; Landauer & Dumais, 1997; Landauer, Foltz, & Laham, 1998).

The present study focuses on the domain of conceptual physics. It should be noted that most modern physics texts (such as Hewitt, 1998) devote considerable space to the historical evolution of physical concepts, the cultural context of physics, and its social impact. Some authors also devote appreciable space to discussing discarded theories and chains of reasoning that lead to incorrect conclusions. Thus, a significant fraction of the text found in a physics text may exemplify incorrect thinking.

The Tutoring Research Group at the University of Memphis has been concerned with the best strategy for selecting a corpus of texts when constructing an LSA space. A naive approach would be to gather a number of physics texts, and combine them into one corpus. However, there are some important, unexplored issues that must be addressed about this approach. What should be done about the text that was written to illustrate incorrect reasoning? Does the inclusion of historical information or peripherally related information strengthen or dilute the accuracy with which physics concepts are represented in the LSA space? In short, how much special preparation of the corpus is needed, if it is to provide a reliable representation of the physics that students are expected to learn?

In this paper, we provide a brief overview of LSA and how it is used in our tutoring system. Then we discuss a study designed to address the matter of corpus selection by systematically testing the kind of texts

needed for a training corpus. We discuss the implications of these results for tutoring systems in general.

Latent Semantic Analysis

LSA has recently been successfully used as a statistical representation of a large body of world knowledge (Kintsch, 1998; Landauer & Dumais, 1997). LSA provides the foundation for grading essays, even essays that are not well formed grammatically or semantically. LSA-based essay graders assign grades to essays as reliably as experts in composition (Foltz, Gilliam, & Kendall, 2000). LSA has been used to evaluate the quality of student contributions in interactive dialogs between college students and AutoTutor. AutoTutor is a tutoring system in the domain of computer literacy and most recently physics (Graesser et al., in press; Graesser et al., 2001). The LSA module evaluates the quality of student answers to questions almost as reliably as graduate research assistants (Graesser, P. Wiemer-Hastings, K. Wiemer-Hastings, Harter, Person, & TRG, 2000; P. Wiemer-Hastings, K. Wiemer-Hastings, Graesser, & TRG, 1999). Having established the utility of LSA in evaluating the quality of student essays and contributions in a tutoring systems on a variety of topics, we are presently interested in exploring what qualities a useful LSA space must have.

LSA is a mathematical technique in which the information contained in the co-occurrences of words in a body of text is compressed into a set of vectors in N -dimensional space. The input to LSA is a word co-occurrence matrix M , where the individual elements M_{ij} is the number of times that the i th word occurs in the j th document. A document is an arbitrarily defined unit, but normally is a sentence, paragraph, or section in a text; for this project we used paragraphs as our document size. The rows and columns of the matrix are then subjected to mathematical transformations that take into account the frequency of the words used in each of the documents (Berry, Dumais, & O'Brien, 1995; Landauer et al., 1998). Using the mathematical technique of singular value decomposition, the matrix is then expressed as the product of three matrices, the second of which contains the singular values on the diagonal. Changing all but the largest N singular values to zero sets the dimensionality N of the vector space representing the text. The matrices are then re-multiplied to produce a matrix of the same dimensions of the original matrix.

By removing the lowest of the singular values we are seem to be eliminating spurious co-occurrences and capturing a more accurate representation of the meaning of the text (Landauer & Dumais, 1997). The reduced number of dimensions is sufficient for evaluating the conceptual relatedness between any two bags of words. A bag is an unordered set of one or more

words. The match (i.e., similarity in meaning, conceptual relatedness) between two bags of words is computed as the geometric cosine (or dot product) between the two associated vectors, with values that normally range from 0 to 1. LSA cosine values successfully predict the coherence of successive sentences in text (Foltz, Kintsch, & Landauer, 1998), the similarity between student answers and ideal answers to questions (Graesser, P. Wiemer-Hastings, et al., 2000; Wiemer-Hastings et al., 1999), and the structural distance between nodes in conceptual graph structures (Graesser, Karnavat, Pomeroy, Wiemer-Hastings, & TRG, 2000).

At this point, researchers are continuing to explore the strengths and limitations of LSA in representing world knowledge. For example, it is widely accepted that LSA is not equipped to handle syntax, word ordering constraints, Boolean expressions, negation, or other precise analytic expressions.

Overview of AutoTutor

In order to fully understand how we use LSA in AutoTutor, it is beneficial to understand the framework in which it is used. Therefore, we briefly provide a general overview of the AutoTutor architecture. A more thorough description is provided in previous publications (Graesser, Person et al., in press; Graesser et al., 1999; Wiemer-Hastings et al., 1998). AutoTutor's style of tutoring was modeled after actual human tutoring sessions (Graesser et al., 1995). The tutor starts out by asking a question or posing a problem that requires a paragraph-length answer. The tutor then works with the student to cover the essential points that the tutor deems necessary to adequately understand the answer to the question. When a question is answered, the process is repeated for a subsequent question. Since most human tutors are peers of the students, they are not what one would label as experts. Thus, they typically have a limited understanding of what the students are trying to convey, yet, they can typically determine whether a response is "in the ball park". Despite the lack of complete understanding, survey studies have shown a sizable advantage for face-to-face tutoring sessions over classroom situations (Cohen, Kulik, & Kulik, 1982).

The user interface for AutoTutor attempts to recreate this face-to-face environment. It consists of four windows: one for presenting the main question, a second for displaying animated or static graphics (simulating diagrams or drawings that a tutor might use to illustrate points), a third with an animated conversational agent, and a fourth for the student to type a reply. AutoTutor's animated agent has synthesized speech, a head, hands, and can be seen from the chest up. These features were designed to provide appropriate speech, facial reactions, and hand

gestures so the student gets both verbal and visual feedback in order to enhance and more appropriately mimic a one-on-one tutoring environment.

AutoTutor's knowledge of its tutoring domain resides in a curriculum script. This is a list of the questions or problems that the tutor is prepared to handle in a tutoring situation, along with good answers to the questions and problems (Putnam, 1987). A major portion of the script is the LSA space; it gets created from an assortment of texts collected from the domain of interest. This corpus is a set of general, non-specific information on the subject matter (e.g., a textbook on conceptual physics), plus specific information directly relevant to the curriculum script. This specific information is comprised of a relatively lengthy, complete, "ideal" answer. This complete answer is separated into a set of specific good answers which address one aspect of the ideal answer; these are sometimes called expectations or points. There are also a set of bad answers and how they would be corrected. Finally, for each expectation in the ideal answer, there are hints, prompts, and assertions that help the student construct an appropriate answer. There are a variety of other dialog moves and slots in the curriculum script that need not be addressed in the present study.

It is important to mention that the LSA corpora investigated in the present study included the general information from textbooks, but never included the question specific information. Thus, only the general physics information was trained in the LSA space. It could be argued that an LSA space should not have any trouble accounting for the content in the curriculum scripts (even if it was a small script) if the material included in the corpus was tailored specifically to the problems. Therefore, we are exploring how far we can go by exclusively focusing on the general content of physics, as manifested in a textbook on conceptual physics.

So how does AutoTutor use LSA during the tutorial interaction? Using the LSA derived cosine matches, AutoTutor evaluates the quality of the student's contributions within a conversation turn and across turns with respect to expected good answers and bad answers to the question. Based on values of these cosine matches, appropriate dialog moves are executed, such as feedback (positive, negative, neutral), pumps, prompts for specific words, hints, assertions, summaries, corrections, and follow-up questions. The smoothness of the mixed-initiative dialog in AutoTutor critically depends on the fidelity of the LSA space. This of course motivated us to test the performance of the LSA space on various tasks and measures.

Methods

Participants. Participants were 120 students from The University of Memphis and Rhodes College; 80 of the students were non-physics majors and 40 were physics majors. Each participant answered 10 problems that were randomly selected from a set of 53 physics problems. Four physics experts answered all 53 questions and graded all answers on a standard 5-point grading scale (A, B, C, D, F). The interrater reliability of the experts was $r = .72$. In the performance tests of LSA, we compared the expert ratings of the student answers to the LSA cosine scores. The LSA cosine scores are a match between the student answer and the ideal answer (i.e., answers created by the experts). The 4 experts had graduate degrees in physics (2 masters and 2 doctoral).

Materials. We have assembled five different physics corpora to test the effect of the content of the subject matter on the quality of the LSA solutions. The documents in the texts were classified into different rhetorical categories, such as exposition, example problems, historical material, incorrect reasoning, and so on. The fundamental research question is whether the inclusion of different texts and the resulting purity of content will have an impact on the tests of LSA performance.

All the corpora include text materials from the mechanics portion of Paul Hewitt's *Conceptual Physics* (1998). This text is widely used in conceptual physics courses at the college level. Our largest corpus, designated as "All", included chapters 2-9 of the Hewitt book plus six volumes of a comprehensive text aimed at students in technical or life science majors, two advanced texts in electromagnetism, and another two physics texts that were available electronically, a general text by Benjamin Crowell and more advanced text by Frank Firk. A somewhat smaller corpus (designated as "Hewitt-Crowell (6)") was constructed from the former by deleting four of the texts; these texts were considered peripherally related to our conceptual physics domain because they were advanced texts mainly dealing with electromagnetism rather than mechanical physics. An even smaller corpus (designated "Hewitt-Crowell (2)") was created by further deleting chapters that did not cover mechanics. Next, we deleted any material from the remaining text that was identified by a physics professor as being primarily historical or involving misconceptions. This was our sanitizing procedure and resulted in the "Hewitt-Crowell (2-Sanitized)" corpus. Finally in the "Hewitt (Sanitized)" corpus, we included only those texts from Hewitt that had been sanitized. It should be noted that each of the successively refined or sanitized corpora was a proper subset of the preceding one. Table 1 summarizes the composition of the five corpora in addition to reporting

the number of paragraphs and the number of unique terms.

Table 1. List of five physics corpora via the chapters that comprise them. Columns with triangles signify sanitized corpora while squares signify unsanitized corpora.

Measures. The performance measure was computed on the set of answers to the 53 questions. Since there were 53 questions and approximately 20 answers per question, there was a set of approximately 1000 answers. Each answer was rated by the 4 experts on a 5 point scale (1 = F and 5 = A); the final grade for the answer was the mean grade of the 4 experts. We refer to this score as the grade of the answer. Also associated with each answer was an LSA coverage score, this score compared each student answer to the set of expectations in the experts' answers to the question. More specifically, each expert answers was segregated into a set of expectations, with each expectation being one sentence. An expectation was scored as "covered" if the LSA score between any sentence in the student answer and the expectation under consideration had an LSA cosine score that was greater than or equal to some threshold T . The extent to which student answer S

matched expert answer A was computed as the proportion of expectations in A that had LSA matches that met the threshold (see Graesser et al., 2000). There were 4 of these scores, one for each of the 4 experts. The maximum value of these scores was designated as the LSA coverage score for student answer S . Moreover, we varied the thresholds in these computations from .3 to .9 in increments of .1 (see Figure 1). The correlation between the grades of the answers and the LSA coverage scores was the critical performance measure for the LSA space. The higher the correlation, the better the performance of the LSA space.

Results and Discussion

We tested 5 different physics corpora, each having a slightly different level of specificity in the domain of conceptually based mechanical physics. Because the size of the corpus could affect the dimensionality and threshold, we tested the performance of all 5 levels of corpus size on 5 different dimensionalities (100, 200, 300, 400, and 500), and 7 critical threshold values, from 0.3 to 0.9 in 0.1 increments. For each combination of these factors, we computed the correlation between the grades and the LSA coverage scores.

Figure 1 plots performance for each level of corpus size by threshold at 300 dimensions. We used 300 dimensions for two reasons. First, the sanitized Hewitt corpus was so small that nothing higher than a 300 dimensional representation could be obtained. Second, the performance did not improve after 300 dimensions on any of the corpora. As Figure 1 shows, the LSA performance was practically identical for all corpus sizes except the smallest. Thus, it was not necessary to eliminate historical material, explanations of discarded theories, or useful demonstrations of incorrect chains of reasoning. There was no payoff in sanitizing the corpus.

The size of the corpus had a modest impact on the correlations, except for the extremely small corpus. Clearly the amount of text and the performance of LSA is not a linear relation. A relatively small amount of relevant material can produce acceptable performance with LSA.

According to the results in Figure 1, it appears that a threshold of approximately .8 provides a reasonable fit to the data. Thus, a sentence-like expectation is regarded as covered if there is a sentence in the student answer that has an LSA match score of .8 or higher.

In summary, we have developed a number of alternative physics text corpora for use in the evaluation of student answers to physics questions. Comparisons of the expert grades of the student answers and the computed LSA coverage scores suggest that the inclusion of material that is historical in nature or that exemplifies incorrect notions of physics does not hamper the performance the LSA space. It was also

surprising that the space performed as well as it did considering that there was no problem-specific information in the set of texts used for training the LSA space. Furthermore, a relatively small space in the restricted domain of physics contains enough information to mine an appropriate co-occurrence matrix and produce a properly functioning LSA space. Our current plan is to follow up this experiment by investigating how much performance is improved by adding the specific curriculum script information.

Figure 1: Correlation between the average expert grade and the student's LSA coverage score as a function of threshold and corpus of texts.

Experience and Pseudo-Experience: Exemplar Effects Without Feedback

Henrik Olsson (henrik.olsson@psy.umu.se)

Abstract

Many real world situations do not offer unambiguous outcome feedback on how to categorize objects. Models in the categorization literature have mostly been formulated for tasks with trial-by-trial outcome feedback. We examined if there was evidence for exemplar memory also when no external feedback is provided and the criterion is derivative of more abstract knowledge. In a "teacher-student" task, a teacher learns how to judge the toxicity of bugs from external outcome feedback and conveys this knowledge to a student that receives no outcome feedback. The results showed that the students exhibit exemplar effects even if the instructions from the teachers were in the form of rules.

Introduction

Consider listening to your very first speech by a politician. Your previous knowledge is likely to influence your attitude towards her or him. Perhaps, already from childhood your father has imprinted in you that politicians are guided by strictly egoist motives and your general conceptions thus include a belief that no politician advocates a proposal that does not lay in his or her personal interest. You hear a short speech that is neutral in content. Later you listen to another politician. How is your opinion of this second politician influenced by the first encounter? You did not receive much useful feedback from the first encounter, as you only listened to a short neutral speech. However, in your memory the first politician is stored as a person only interested in pursuing his own interest. This exemplar memory only in part derives from direct experience with a politician; in part it is derivative of more general beliefs held prior to the encounter. However, by now this belief is supported also by "concrete experience" of politicians.

This was an example of a real world situation that is different from most categorization experiments where classification models are tested in tasks with simple perceptual stimuli and trial-by-trial outcome feedback. Everyday situations often do not offer direct and unambiguous feedback and exemplar memory is thus likely to derive in part also from other sources of knowledge besides concrete experience with the objects.

There has been increasing interest in multiple representation levels (e.g., Ashby, Alfonso-Reese, Turken, & Waldron, 1998) and there is evidence that people can adaptively shift between different representation levels

in response to the experimental demands (Jones, Juslin, Olsson, & Winman, 2000). With experience, knowledge first represented abstractly may be projected onto concrete exemplars so that in the end the beliefs are supported also by an extensive exemplar memory: a phenomenon that might be called *pseudo-experience*.

Even if some extensions of exemplar models allows for storage of exemplars as they are interpreted and not solely in terms of their physical properties (e.g., the model presented by Smith & Zarate, 1992), the argument supporting this claim is based on general observations and not linked to predictions from different models. For example, one such observation is that a re-encounter of a stimulus facilitate the same reactions and processes (see the review in Smith & Zarate, 1992).

In this paper, we examine the possibility of extending the scope of *exemplar models* (Medin & Schaffer, 1978; Nosofsky, 1986) to situations where people do not receive outcome feedback, but form beliefs about the criterion from abstract knowledge of rules. In these circumstances, one possibility is that people completely abandon exemplar processes as a basis for their judgments and directly use abstract knowledge in the form of rules or prototypes.

Another possibility is that people generate the criteria from abstract knowledge and store them together with the experienced exemplars; later to rely on these stored exemplars to make their judgments. We explore these possibilities in a "teacher-student" task where a teacher learns how to judge the toxicity of bugs from outcome feedback and the student has to rely on *feedforward* summary information provided by the teacher. The question is if there is evidence for exemplar processing in the students judgments even if they do not receive feedback or instructions about exemplars from the teachers.

Measuring Exemplar Effects

To develop an exemplar effect index we need to consider a category structure that allows us to differentiate between predictions by the exemplar model and other plausible models, in this case a cue-abstraction model that linearly integrates cues. The results previously obtained with this task revealed large individual differences and a shift from exemplar memory to more mental cue-integration processes when the criterion is changed from classification to a continuous judgment task (Juslin, Olsson, & Olsson, 2002).

The task requires participants to use four binary cues to infer a continuous criterion. (Juslin et al., 2002). The judgments involve the toxicity of subspecies of a fictitious Death Bug. The different subspecies vary in concentration of poison from 50 ppm (harmless) to 60 ppm (lethal). The toxicity can be inferred from four visual cues of the subspecies (e.g., the length of their legs, color of their back).

The binary cues C_1 , C_2 , C_3 , and C_4 take on values 1 or 0. The toxicity c of a subspecies is a linear, additive function of the cue values:

$$c = 50 + 4 \cdot C_1 + 3 \cdot C_2 + 2 \cdot C_3 + 1 \cdot C_4 \quad (1)$$

C_1 is the most important cue with coefficient 4 (i.e., a relative weight .4), C_2 is the second to most important with coefficient 3, and so forth. A subspecies with feature vector (0, 0, 0, 0) thus has poison concentration 50 ppm; a subspecies with feature vector (1, 1, 1, 1) has 60 ppm. The continuous criteria for all 16 subspecies (i.e., possible cue configurations) are summarized in Table 1.

Table 1
Structure of the Task

Exemplar	C_1	C_2	C_3	C_4	Criterion	Exemplar type
1	1	1	1	1	60	E
2	1	1	1	0	59	T
3	1	1	0	1	58	T
4	1	1	0	0	57	O
5	1	0	1	1	57	N
6	1	0	1	0	56	N
7	1	0	0	1	55	N
8	1	0	0	0	54	T
9	0	1	1	1	56	O
10	0	1	1	0	55	O
11	0	1	0	1	54	T
12	0	1	0	0	53	T
13	0	0	1	1	53	T
14	0	0	1	0	52	T
15	0	0	0	1	51	T
16	0	0	0	0	50	E

Note: C = Cue; E = Extrapolation; T = training exemplar; O = Old comparison exemplar in training, N = New comparison exemplar presented at test.

In *training*, the participants encounter 11 subspecies and make *continuous judgments* about the toxicity of each subspecies ("The amount of poison is 57%"). As indicated in the two right-most columns of Table 1, five subspecies are omitted in training. In a *test phase*, the participants make the same judgments as in the training phase, but for all the 16 subspecies and without feedback. The task allows perfect performance in training both by exemplar memory and induction of the task structure (i.e., by inducing the cue weights in Eq. 1).

The *exemplar model* implies that participants make judgments by retrieving similar exemplars (subspecies) from long-term memory. The *context model* of classification (Medin & Schaffer, 1978) suggests that in a task

that only requires participants to judge if a bug is dangerous or not, the probability $p_E(b=1)$ of categorization as dangerous (1) equals the ratio between the summed similarity of the judgment probe to the dangerous exemplars and the summed similarity to all exemplars:

$$p_E(b=1) = \frac{\sum_{j=1}^J S(p, x_j) \cdot b_j}{\sum_{j=1}^J S(p, x_j)} \quad (4)$$

where p is the probe to be judged, x_j is stored exemplar j ($j=1 \dots J$), $S(p, x_j)$ is the similarity between the probe p and exemplar x_j , and b_j is the binary criterion stored with exemplar j ($b_j=1$ for dangerous, $b_j=0$ for harmless). J depends on the size of training set of exemplars.

The similarity between probe p and exemplar x_j is computed by the multiplicative similarity rule of the context model (Medin & Schaffer, 1978):

$$S(p, x_j) = \prod_{i=1}^4 d_i \quad (5)$$

where d_i is an index that takes value 1 if the cue values on cue dimension i coincide (i.e., both are 0 or both are 1), and s_i if they deviate (i.e., one is 0, the other is 1). s_i are four parameters in the interval [0, 1] that capture the impact of deviating cues (features) on the overall perceived similarity $S(p, x_j)$. s_i close to 1 implies that a deviating feature on this cue dimension has no impact at all on the perceived similarity and is considered irrelevant. s_i close to 0 means that the overall similarity $S(p, x_j)$ is close to 0 if this feature is deviating, assigning crucial importance to the feature. The parameters s_i capture the similarity relations between stimuli and the attention paid to each cue dimension, where a lower s_i signifies higher attention.

The context model was developed for classification, in most cases to binary categories. To generate predictions also for judgments of a continuous criterion we relax the model by allowing the outcome index b_j to take not only binary but also continuous values. The estimate \hat{c}_E of the criterion c is a weighted average of the criteria c_j stored for the exemplars, where the similarities $S(p, x_j)$ are weights (see e.g., Juslin & Persson, 2000; Smith & Zarate, 1992, for similar applications).

The *cue-abstraction model* assumes that the participants abstract explicit cue-criterion relations in training, which are mentally integrated at the time of judgment. When presented with a probe the participants retrieve rules connecting cues to the criterion from memory (e.g., "Green back goes with being poisonous"). The rules specify the sign of the relation and the importance of each cue with a cue weight. For example, after training the rule for cue C_1 may specify that $C_1=1$ goes with a large increase in the toxicity of a subspecies.

Cue abstraction implies that participants compute an estimate \hat{c}_R of the continuous criterion c . For each cue, the appropriate rule is retrieved and the estimate of c is

adjusted according to the cue weight ω_i ($i=1\dots 4$). The final estimate \hat{c}_R of c is a linear additive function of the cue values C_i ,

$$\hat{c}_R = k + \sum_{i=1}^4 \omega_i \cdot C_i, \quad (2)$$

where $k = 50 + .5 \cdot (10 - \sum \omega_i)$. If $\omega_1=4$, $\omega_2=3$, $\omega_3=2$, and $\omega_4=1$, Eq's 1 and 2 are identical and the model produce perfect judgments. The intercept k constrains the function relating judgments to criteria to be regressive around the midpoint (55) of the interval [50, 60] specified by the task instructions.

Figure 1: Panel A: Cue abstraction model predictions for the constrained training set. Panel B: Exemplar model predictions with similarity parameter $s=.1$ for the constrained training set. O = Old comparison exemplar in training, N = New comparison exemplar presented at test, E = Extrapolation exemplars.

The predictions from the two models are summarized in Figure 1 and shows that the models predict distinct patterns. The cue abstraction model allows accurate extrapolation beyond the distribution of criteria in the training set [51, 59]. Whenever the correct signs of the cue weights are identified, the most extreme judgments are made for exemplars 1 and 16. The exemplar model, that computes a weighted average of the criteria observed in training, can never produces a judgment outside the observed range. The most extreme judgments are made for criteria $c=51$ and 59.

Moreover, with cue abstraction there should be no systematic differences between judgments for "New" and "Old" exemplars with $c=55, 56$, and 57: the process is the same in both cases. However, with the exemplar model there is more accurate judgments for Old exemplars, because these judgments benefit from retrieval of identical exemplars with the correct criterion.

These differences in predictions allow us to define measures of the amount of exemplar processing. First, The old-new difference index ΔON is defined as,

$$\Delta ON = \bar{d}_{Old} - \bar{d}_{New} \quad (6)$$

where \bar{d}_{Old} is the mean absolute deviation between judgment and criterion for the three old exemplars and \bar{d}_{New} is the corresponding mean deviation for the three new exemplars in Table 1. When judgments for old

rather than new exemplars are more accurate, the index is negative. The extrapolation index EI is the mean deviation from linear extrapolation,

$$EI = \frac{(x_{51} - x_{50}) + (x_{60} - x_{59}) - 2b}{2} \quad (7)$$

where x_{50} , x_{51} , x_{59} , and x_{60} are the judgments for exemplars with criteria 50, 51, 59 and 60, respectively. The value of b is determined by the difference $x_{51} - x_{50}$ (or equivalently $x_{60} - x_{59}$) predicted by a linear regression relating judgments to criteria. Perfect linear extrapolation implies an extrapolation index that is 0 (e.g., when the judgments are perfectly accurate). If the index is negative, the exemplars with extreme criteria do not receive as extreme judgments as implied by linear extrapolation. For example, the indices in Figures 1A are 0, but the indices in Figure 1B are negative. The mean of ΔON and EI provides a total index of exemplar effects, *Total EE*.

Method

Participants

Forty undergraduate students participated. The participants were paid between 50 and 100 SEK depending on their performance.

Apparatus and Materials

The experiment was carried out on a PC-compatible computer. The exemplars varied in terms of four binary cues; leg length (short or long), nose length (short or long), spots or no spots on the fore back and two patterns on the back. The cues and the cue values in the abstract structure in Table 1 were randomly assigned to new concrete visual features for each new participant. Two types of presentation modes were used, one *analogue* where drawings of the bugs were presented and one *propositional* with written descriptions of the bugs.

Design and Procedure

The task was done in pairs, one participant in each pair was randomly assigned as teacher and the other as student. Half of the teacher-student pairs were randomly assigned to the analogue condition and the other half to the propositional condition.

The written instructions informed the participants that the task involved judgments of the toxicity of subspecies of a Death bug from 50 to 60 ppm and that the difference between teachers and students was that the teacher receives outcome feedback and that the student does not. The participants were also informed that they would receive a minimum payment of 50 SEK and up to 100 SEK depending on the performance of the student. The performance bonus was calculated by taking half the correlation between the students' judgments and the criterion values in the test phase times 100. In addition, the teacher was told that after each training block they were to write down instructions to the stu-

dent on how to assess the toxicity of the bugs as a Word file. The teachers were free to give any instructions they wanted. The word files were collected for further analysis by the experimenter. No additional contacts between teachers and students were allowed (except for strictly clarifying questions in regard to spelling errors, as mediated by the experimenter).

The training phase consisted of four blocks with 55 trials each making a total of 220 trials. Only the teacher received outcome feedback of the correct toxicity level in the learning phase. After each training block the teacher wrote down instructions to the student and the experimenter handed it over to the student that were seated in another room. In the test phase each exemplar were presented four times without feedback for both teachers and students making a total of 64 trials. The entire experiment took from one hour and fifteen minutes to two hours.

Results

Performance for teachers and students in the learning phase of the analogue and the propositional conditions measured by the absolute deviation between judgment and criterion are presented in Figure 2. The performance for teachers and students are about the same in the last part of training. Performance is better in the analogue condition than in the propositional condition.

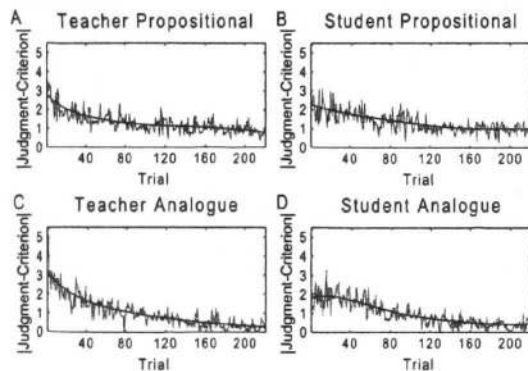

Figure 2: Panels A-D: Mean absolute deviation between judgment and criterion for teachers and students. The curves are fitted according to a negative exponentially weighted smoothing procedure.

Figure 3 shows that there appears to be some exemplar effects in all the conditions, for both teachers and students. The judgments of the new exemplars are less accurate than the old exemplars and underestimate the criteria. The figure also shows that both teachers and students have some difficulties with extrapolating beyond the distribution of criteria in the training set.

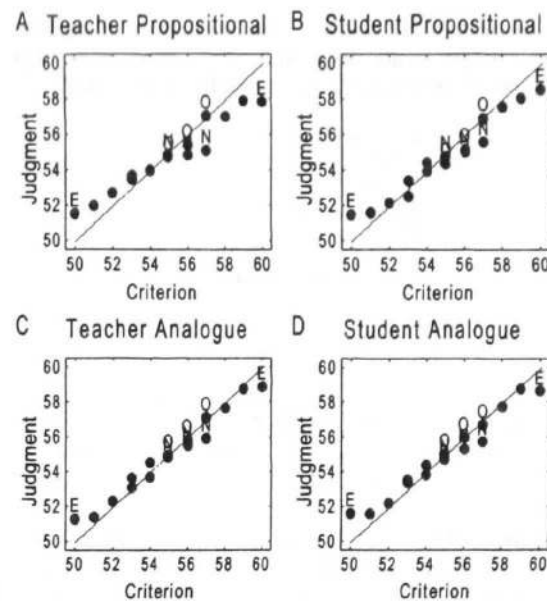

Figure 3: Panels A-D: Mean judgments for the different criteria for teachers and students.

The exemplar indexes were collapsed over the analogue and the propositional conditions as no significant differences were found between the two conditions for any of the indexes. Figure 4 shows that there are clear exemplar effects for both teachers and students, as the 95% confidence intervals does not include zero.

Figure 4: Panel A: Mean Old-New difference index, ΔON . Panel B: Mean extrapolation index EI . Panel C: Mean total exemplar effects index, EE . The error bars are 95% confidence intervals.

We coded the instructions the teachers gave the students as containing exemplars or not by a strict coding scheme that assigned any ambiguous case as an exemplar instruction. Six teachers had instructions containing exemplar information, for example "Green body, short legs, long nose, no spots = 51%". A typical part of

an instruction that did not contain exemplar instruction was "Begin with 50% and add: short grey legs +2...green long legs +0 [and so on for all the cues]".

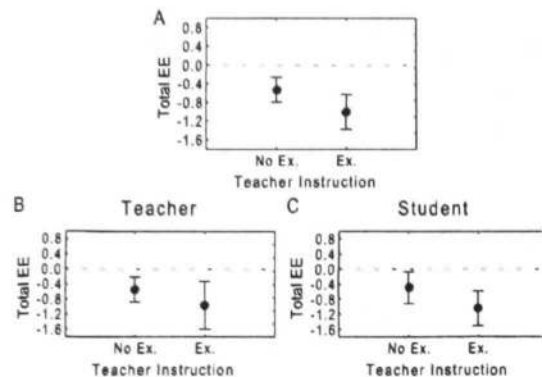

Figure 5: Panel A: Mean total exemplar effects index, *EE*, for No exemplar instructions and Exemplar instructions over all conditions. Panel B: Mean total exemplar effects index, *EE*, for No exemplar instructions and Exemplar instructions for teachers. Panel C: Mean total exemplar effects index, *EE*, for No exemplar instructions and Exemplar instructions for students. The error bars are 95% confidence intervals.

Shown in Figure 5 is the total exemplar effects index separately for the participants with no exemplars in the teachers' instructions and those with exemplars in the instruction. It can be seen that there is an effect of instruction with larger exemplar effects for exemplar instructions, $t(38) = 2.00$, $p = .026$, one-tailed. More importantly, students with no exemplar instructions from their teachers exhibit evidence for exemplar processing, as the confidence intervals do not include zero.

Figure 6: Mean judgments for two students that did not receive any exemplar information. Panel A: A student better described with a cue-abstraction model. Panel B: A student better described with an exemplar model.

Investigation of individual participants data reveals large individual differences. Figure 6 shows two students that did not receive any exemplar information from their teachers. One student is better described as a

cue abstraction participant and the other student as an exemplar participant.

Discussion

In this paper, we have shown that people can spontaneously rely on pseudo-experience in a judgment task. Even when the information people receive does not contain information about specific exemplars, people cannot help project abstract rule knowledge onto concrete exemplars and then use these exemplars in the judgment process.

Even if there are large individual differences in data with some people operating only in accordance with the cue-abstraction model, it seems difficult for most people to totally abandon exemplar processing. Even if you initially execute a rule to determine what response you will make, the very act of executing the rule implies processing the exemplar in front of you. For example, you need to scan the object for features that fit the rule conditions. Even if you do not consciously trying to remember exemplars, the end result is incidental learning of exemplars that later influences judgments.

One caveat is that the types of categories used could affect the prevalence of exemplar based processing. For example, the results in a series of experiments by Minda, Smith and colleagues (e.g., Minda & Smith, 2001) suggest that larger categories, better structured categories, and more complex stimulus promotes prototype processing at the expense of exemplar processing.

In this, and other tasks, rule based representations provide great powers of generalization and communication. One answer why we sometimes cannot avoid storing and using exemplars may be found in the idea that our cognitive system consists of multiple levels of representation that work together or compete to determine responses in specific tasks (see e.g., Ashby et al., 1998). Our results fit into the notion that the exemplar representation has a function that separates it from other representational formats in that it acts like an automatically activated back-up system that preserves distributional and individuating information about the world.

Abstract

A formal model of learning as induction, the simplicity principle (e.g. Chater & Vitányi, 2001) states that the cognitive system seeks the hypothesis that provides the briefest representation of the available data—here the linguistic input to the child. Data gathered from the CHILDES database were used as an approximation of positive input the child receives from adults. We considered linguistic structures that would yield overgeneralization, according to Baker's paradox (Baker, 1979). A simplicity based simulation was run incorporating two different hypotheses about the grammar: (1) The child assumes that there are no exceptions to the grammar. This hypothesis leads to overgeneralization. (2) The child assumes that some constructions are not allowed. For small corpora of data, the first hypothesis produced a simpler representation. However, for larger corpora, the second hypothesis was preferred as it led to a shorter input description and eliminated overgeneralization.

Introduction

Overgeneralizations are a common feature of language development. In learning the English past tense, children typically overgeneralize the '-ed' rule, producing constructions such as *we holded the baby rabbits* (Pinker, 1995). Language learners recover from these errors, in spite of the lack of negative evidence and the infinity of allowable constructions that remain unheard; it has been argued that this favours the existence of a specific language-learning device (e.g. Chomsky, 1980; Pinker, 1989). This is an aspect of the 'Poverty of the Stimulus' argument. We report on a statistical model of language acquisition, which suggests that recovery from overgeneralizations may proceed from positive evidence alone. Specifically, we show that adult linguistic competence in quasi-regular structures may stem from an interaction between a general cognitive principle, *simplicity* (Chater, 1996) and statistical properties of the input.

According to Baker's Paradox (Baker, 1979) children are exposed to linguistic structures that they subsequently overgeneralize, demonstrating that they capture some general structure of the language. However, some generalizations are grammatically incorrect and children do not receive direct negative evidence from caretakers (e.g. corrections labeling such overgeneralizations as disallowed). The paradox is that non-occurrence is not in itself evidence for the incorrectness of a construction because an infinite number of unheard sentences are still correct. The irregularities that Baker referred to can be broadly labeled *alternations* (Levin, 1993; see also Culicover, 2000). For instance, the dative alternation in English allows a class of verbs to take both the double-object construction (*He gave Mark the book*) and the prepositional construction (*He gave the book to Mark*). Hence the verb *give* alternates between two constructions. However, certain verbs seem to be constrained to one possible construction only (*He donated the book to Mark* is allowed, whereas **He donated Mark the book* is not). Such verbs are non-alternating. From empirical studies we know that children do make overgeneralization errors that involve alternations, such as **I said her no* (by analogy to *I told her no*, Bowerman, 1996; Lord 1979).

In this paper we present alternation phenomena from the CHILDES database (MacWhinney, 2000) of child-directed speech which will be used in the computer model. Secondly, we introduce the *simplicity principle* (Chater, 1996), based on the mathematical theory of Kolmogorov Complexity (Kolmogorov, 1965). Thirdly, we present an artificial language designed to model the CHILDES data, and describe simplicity-based models of language processing and the simulations of recovery from overgeneralizations. Lastly we discuss the limitations of this specific model and some implications for research on language acquisition.

Causative alternations in child-directed speech

Suppose we have a language in which verbs belong to three distinct classes (V1, V2, V3). Each class is related to two syntactic contexts (C1, C2). One class of verbs (V1) appears in both contexts. Two other classes of verbs (V2 and V3) occur in one context only. We can produce a simple table to visualize the alternation:

Table 1: Alternating and non-alternating verbs across contexts

	C1	C2
V1	1	1
V2	0	1
V3	1	0

The causative alternation in English is of this kind. Verbs like *break* behave both transitively (*I broke the vase*) and intransitively (*The vase broke*), whereas verbs like *disappear* behave only intransitively (*The rabbit disappeared* is allowed; but **I disappeared the rabbit* is not) and verbs like *cut* are found only in transitive contexts (**The bread cuts* is not allowed). An analysis of CHILDES revealed that verbs in child-directed speech fit the pattern of the above idealization: a number of verbs are exclusively transitive or intransitive (see Table 2).

Children eventually generalize the structures of the language they are exposed to. A typical generalization occurs when children say *Don't you fall me down* (Bowerman, 1982; Lord, 1979). This is an overgeneralized use of a non-causative verb as causative. In the causative construction, some verbs like *break* can be used both transitively with a semantic element of cause (*I broke the vase*) and intransitively (*the vase broke*). Verbs like *break* alternate between two constructions. However, *fall* can only be used intransitively, and *hear* only transitively. The acquisition of verbs' argument structure seems particularly complicated as the way verbs behave syntactically is largely arbitrary. Semantically similar verbs like *say* and *tell*, or *give* and *donate* allow for different constructions.

Bowerman (1982) and Lord (1979) recorded a total of 100 different cases in which two-argument verbs are used with three arguments (e.g. *You can drink me the milk*). The developmental literature suggests that when children acquire a new verb they use it productively in both constructions, without specific directional bias (Lord, 1979). It is also worth noting that alternations can be theoretically distinguished from other forms of Table 2: Verbs in child-directed speech occurring in transitive and intransitive contexts pooled from the CHILDES English sub-corpora (MacWhinney, 2000).

	Verb	Transitive occurrences	Intransitive occurrences
Category V1	bounce	75	117
	break	1251	268
	burn	86	60
	close	855	56
	freeze	18	61
	grow	59	330
	move	966	560
	open	1590	232
	pop	104	153
	rip	139	9
	roll	405	164
	shake	147	26
	slide	65	120
	swing	38	96
Category V2	tear	167	20
	turn	2690	600
	arrive	0	41
	come	0	18437
	dance	0	370
	die	0	141
	disappear	0	73
	fall	0	2945
	go	0	65193
	rise	0	14
Category V3	run	0	1569
	stay	0	1413

irregularization like the irregular past tense. In the case of *goed-went* for example, recovery from the overgeneralized form **goed* can be accounted for by directly invoking a competition strategy (MacWhinney, 1987): as the number of *went* in the input increases, it will win over the irregularized form *goed*, which has 0 frequency in the input. Alternations are interesting theoretically in that the competition model does not seem applicable for these. The overgeneralized form does not have an irregular alternative: there is simply a "hole" in the language. This argument was raised by Baker in his distinction between benign exceptions (like

the past tense) and truly problematic alternations like the ones we consider here (Baker 1979).

For the purpose of showing how such problematic irregularities can be learnt using a simplicity principle, we take the causative alternation described above as a working example. We extracted verb frequencies from the CHILDES Database. CHILDES contains a total of nearly ten million words of child-directed speech. Because we are interested in showing that the input the child receives is rich enough for recovery of overgeneralization by induction, only the adult speech in the corpus was selected and analysed.

Simplicity and Language

The simplicity principle (Chater, 1996) states that in choosing among potential models of finite data, there is a general tendency to seek simpler models over complex ones and optimize the trade-off between model complexity and accuracy of model's description (i.e. fit) to the training data. Complexity is thus defined as:

$$C = C(\text{model}) + C(\text{data}|\text{model})$$

The favoured model of any finite set of data will be that which minimizes this term.

In order to compare different grammars we need a measure of simplicity and a "common currency" for measuring both the model complexity and the error term complexity. Fortunately this is possible by viewing grammar induction as a means of *encoding* the linguistic input; the grammatical organization chosen (the "knowledge" of the language) is that which allows the simplest encoding of the input. A tradition within mathematics and computer science, Kolmogorov complexity, shows that the simplest encoding of an object can be identified with the shortest program that regenerates the object (Li & Vitanyi, 1997).

Every sentence generated from a lexicon of n words may be coded into a binary sequence. The length of a message refers to a binary string description of the message in an arbitrary universal programming language. The binary string can be seen as a series of binary decisions needed to specify the message; smaller lengths correspond to simpler messages. The brevity of an input A_i is associated to its probability $P(A_i)$ of occurrence. Shannon's (1948) noiseless coding theorem specifies that:

$$\text{Length} = \text{Log}_2[1/P(A_i)]$$

More probable events are therefore given shorter codes. Li & Vitanyi (1997) have shown that the length $K(x)$ of the shortest program generating an object x is also related to its probability $Q(x)$ by the following *coding theorem*:

$$K(x) = \text{log}_2[1/Q(x)]$$

Finally, the *invariance theorem* (Li & Vitanyi, 1997) assures that the shortest description of any object is *invariant* (up to a constant) between different universal languages, thus granting a measure of simplicity that is independent of the data and of the programming language used to encode the data. The above formalizations allow us to replace "Complexity" with "Length" and state that "the best theory to infer from a set of data is the one which minimizes the length of the theory and the length of the data when encoded using the theory as a predictor for the data" (Quinlan and Rivest, 1989; Rissanen, 1989). It is important to note that whilst the MDL principle is well established as a machine learning tool for grammar induction, such models typically make use of parsed corpora or other psychologically implausible inputs (e.g. Osborne, 1999). This paper uses MDL as a metric to present simplicity as a specifically psychological principle.

Modelling language learning with simplicity

In any study of grammar induction, and in particular in the simplicity framework, it is crucial to see a grammar as a *hypothesis about the data*. The best hypothesis is the one that compresses the data maximally, so we can also think of a grammar as compression of the data. We can see the achievement of adult linguistic competence as a process of building different hypotheses about the language in order to achieve optimum compression. The essence of compression is to provide a shorter encoding of the data, enabling generalizations and correct predictions. Alternations are particularly informative about the possibility of a cognitive system to capture dependencies from limited data. If linguistic structures were completely regular, then generalizing from a few data would be easy. But as alternations are quasi-regular, meaning there are exceptions to their regularity, a learner must capture fine dependencies in order to generalize whilst avoiding overgeneralizations.

The issue is to choose the candidate model of the right complexity to describe the corpus data, as stated by the simplicity principle. We can compare different hypotheses (grammars) at different stages of learning and choose, for each stage, the one that minimizes the sum of the grammar-encoding-length and the data-encoding-length. In the following section we compare data compression of corpora by two similar models. The difference between them is that one posits a completely regular rule, whilst the other posits a regular rule and some exceptions to it. We can think of the second model as having 'invested' in exceptions. Each exception initially produces less compression overall,

since the exceptions cost some bits to specify. However, each exception shortens the code-length for each item in the corpus, and the second model thereby 'recoups' its investment over time.

The Models

This approach to language acquisition does not focus on how learning occurs. Rather, these simulations run several models concurrently to show that the rate of increase of code-length differs between hypotheses about language. This section describes the structure of two hypotheses (grammars); the first gives rise to overgeneralization phenomena whilst the second does not. These were designed in conjunction with a very simple artificial language, which was subsequently used to test the models. A brief outline of the language is given here to facilitate the description of the model. A more detailed consideration of how the artificial language relates to data from corpora of child-directed speech is given below.

The artificial language used consists of two syntactic categories. These can be thought of crudely as nouns and verbs. They can be combined to form two-word sentences. Sentences may be of the form NV or VN. Forms NN and VV are disallowed. In addition, a number of sentences are disallowed. Let us imagine that there are four nouns (n_1 - n_4) and four verbs (v_1 - v_4) in the language, and that v_4 is blocked in the sentence final position. From this it follows that four sentences are disallowed: each of the four nouns in combination with v_4 in an NV-type sentence.

Each model is comprised of 4 elements: word-level categories, sentence-level categories, exceptions, and code-length. Both models described here contain two word-level categories, comprising nouns and verbs and two sentence-level categories comprising the two sentence types (NV and VN). The exceptions category discretely specified all the disallowed sentences. In the first model this was an empty set. The code-length specified length of code, in bits, that would be needed to specify models just described and the corpus data given the model structure. The code-length for each sentence in the corpus is consequent on the model structure.

Calculating Code-Length For Each Element

The length of code necessary to specify any object, i , is given by:

$$\text{Bits}(i) = \log_2(1/p_i) \quad [1]$$

where p_i is the probability of object i . In many cases described below, p_i can be thought of as choosing one of I options. Where this is the case,

$$\text{Bits}(i) = \log_2 I \quad [2]$$

This section describes how this formula is applied to calculate the code-length for each section of the model and for the data given the model.

If a language contains r word types and n syntactic categories, then the probability of specifying one distribution of word types into categories is the inverse of the number of ways in which r word types can be distributed between n categories, assuming no empty sets. This given by:

$$\text{Distributions}(r, n) = \sum_{v=0}^n (-1)^v \frac{(n-v)^r}{(n-v)! v!} \quad [3]$$

The code-length for the word-level element is therefore:

$$\begin{aligned} &\text{Word-level bits}(r, n) \\ &= \log_2 \sum_{v=0}^n (-1)^v \frac{(n-v)^r}{(n-v)! v!} \quad [4] \end{aligned}$$

Specifying a particular sentence-level rule (e.g. that a sentence may be of the form NV) is a function of the probability of that sentence type given the number of categories specified in the word-level element. Given that in the artificial language sentences only ever contain two words, there are four sentence types possible from two syntactic categories (NN, NV, VN, VV). The probability of any sentence type (e.g. NV) is therefore 1/4. When this has been specified, the probability any remaining sentence type (e.g. VN) is 1/3. The code-length for specifying two sentence types is therefore:

$$\text{Sentence-level bits} = \log_2(4) + \log_2(3) \quad [5]$$

Specifying the cost of an exception is the same as specifying the cost of a sentence. This is done by specifying the cost, in bits, of the first word based on the probability of its occurrence, and the cost of the second word in the same way. The probability of a word's occurrence is the inverse of the total number of possible words. The term to specify the first word in any sentence is therefore:

$$\text{Bits}(i1) = \log_2(T_w - T_{e1}) \quad [6]$$

where $\text{Bits}(i1)$ is the bits required to specify word i in the first position, T_w is the total number of word types in the language and T_{e1} is the total number of words blocked in the sentence initial position as listed in the exceptions category.

The first word specifies which sentence type is being used. The pool of possible words from which the second word must come is therefore reduced to the size of the sentence final category as defined by the sentence type. For example, if the first word in a sentence is a noun, the sentence type must be NV and the second word must therefore be from the category V. The term to specify the second word in a sentence is therefore:

$$\text{Bits}(j/2) = \log_2 (T_{wc} - T_{e2|1}) \quad [7]$$

where $\text{Bits}(j/2)$ is the number of bits required to specify word j in the second position, T_{wc} is the total number of word types in category c , and $T_{e2|1}$ is the total number of words specified in the exceptions element as blocked in position two given the word in position 1. The number of bits for specifying any sentence i, j is simply:

$$\text{sentence bits}_{ij} = \text{Bits}(i/1) + \text{Bits}(j/2) \quad [8]$$

Specifying the code length for each exception is the same as specifying code length for a sentence *given the existing exceptions*. Each exception in a list of exceptions therefore requires slightly fewer bits to code than its predecessor.

It is important to note that these models code corpus data in batch mode – the order in which sentences are coded is not taken into account. A more psychologically realistic (i.e. incremental) algorithm might make use of the fact that frequently occurring words have a higher probability of occurrence and therefore cost less to code.

Simulating recovery from overgeneralization with an artificial language

The models described above were implemented in a computer program. They were then exposed to successively large corpora of sentences from an artificial language which reflected the structure of the transitive/intransitive alternation phenomena found in the CHILDES database (see Table 2, above). A model using raw CHILDES data would have been computationally impossible, but it is important to note that the artificial language closely mirrored the patterns of Table 2. The artificial language is outlined above. In these simulations the word-level categories contained 36 verbs, reflecting the number of verbs in Table 2, and 36 nouns. It was decided to keep the number of nouns equal to the number of verbs in order to avoid disparity between the code-length necessary for different sentence types. There were two sentence-types (NV and VN) reflecting the transitive and intransitive contexts of the verb constructions. Ten verbs were blocked with all 36 nouns for each sentence type (see Table 2), resulting in a total of 720 disallowed sentences.

Two of the four-element models described above were exposed to increasingly large corpora of this language. The first model contained word-level information about the 36 nouns and verbs, and sentence-level information about the NV and VN sentence types, but the exceptions element was empty: it did not contain any information about the 720 disallowed sentences. In this respect it was analogous to a learner who has acquired knowledge of word categories and sentence production rules, but has not learned that some sentences are illegal. This model would therefore be prone to overgeneralizations such as *I disappeared the rabbit*. The second model, by contrast, did contain information about the disallowed sentences. This model therefore required considerably more bits to specify initially, but the number of bits required to specify each sentence of the corpus was fewer. In addition, a language learner who had learned these exceptions would not make the same overgeneralization errors that the first model would. Table 3 shows the relative simplicity of each model for increasingly large corpora as measured by the number of bits necessary to encode the model and the corpus data.

Table 3: Code-lengths of Models 1 and 2 for successively large corpora. Code-lengths in bold show the shorter codes for the corpus size

Corpus Size (sentences)	Model 1: Codelength (bytes)	Model 2: Codelength (bytes)
0	0.1	7.6
4000	45.4	51.1
8000	90.8	94.7
12000	136.2	138.3
16000	181.5	181.8
20000	226.9	225.4
24000	272.2	268.9

It can be seen that for relatively small corpora (up to about 16,000 sentences), Model 1 gives a simpler encoding: less bits are required. For a learner who had heard relatively few alternation constructions, therefore, the tendency would be to code the data in these terms, resulting in overgeneralizations. For a more experienced learner, however, the simpler encoding would be that shown by Model 2, which requires less bits to encode relatively large corpora. The model does not produce any language, so there are no accuracy statistics. Rather, it is assumed that the learner produces all the sentences available in the current (shortest) hypothesis are produced, including any that are incorrect.

Conclusions and future directions

These results provide an initial confirmation that simplicity may provide a guiding principle by which some aspects of language may be learned from experience without recourse to a specific language-learning device. However, the simulations presented here are coarse-grained approximations of both the language and the language learner. Children do not process the language in batches of several thousand utterances. The models presented here were neither exposed nor sensitive to different word-type frequencies. A number of further studies which would provide considerably firmer support for the simplicity principle as a driving force for language acquisition suggest themselves.

Firstly, mathematical results show that word-type frequencies are important to the simplicity-driven learner, in that they may be the key as to when it becomes advantageous to posit exceptions to rules. Chater and Vitányi (2001) show that languages are approximately learnable given sufficiently large amounts of data. The CHILDES data in Table 2 therefore provides an indication of the order in which one would expect the learner to cease overgeneralizing words. An examination of children's speech that confirmed this order would be a major step towards providing robust support for the simplicity principle in language. Secondly, it would be useful to compare the timescale of recovery from overgeneralization in children with that of the model. This could be done by an examination of CHILDES database to determine an approximate relation between a child's age and the number of transitive/intransitive alternation constructions to which they have been exposed. It would then be possible to compare the learning rate of the child with that of the model. Again, this would be a useful source of evidence concerning the simplicity principle in language.

In this paper we have suggested that there is sufficient statistical information in the input for a learner to learn quasi-regular alternating structures. These results are achieved by choosing the model of the language which provides the simplest (shortest) description of the linguistic data that has been encountered. These results re-open the question of the viability of language learning from positive evidence under less than ideal conditions, with limited computational resources and amounts of linguistic data available. They therefore also bear, indirectly, on the arguments concerning the balance between nativism and empiricism in language acquisition. More concretely, we suggest that the working hypothesis that the search for simplicity is a guiding principle in language acquisition deserves serious attention.

Psychology Department, Old Dominion University
Norfolk, VA 23529 USA

Abstract

This study examined the influence of cognitive ability and student activities on high-school students' science achievement. Students ($n=1651$) from four high schools in three states were assessed in terms of their cognitive abilities (i.e., science knowledge, reading skill, and metacognitive reading strategies), course involvement, reading interest, and TV habits. Science achievement was measured in terms of students' course grade, comprehension of a science passage, and performance on a statewide standards of learning (SOL) test. Course involvement significantly predicted only course grade, whereas reading interest predicted SOL scores and science passage comprehension. Cognitive abilities and TV habits predicted all three of the student achievement measures. However, the effects of these cognitive variables interacted in interesting ways.

Introduction

In recent years, scientists have become increasingly interested in uncovering factors that are important for predicting educational success (e.g., Buckner, Bassuk, & Weinreb, 2001; Herman & Tucker, 2000). For example, researchers have reliably predicted academic achievement with measures of student personality (Paunonen & Ashton, 2001; Stewart, Bond, Deeds, Westrick, & Wong, 1999), parental influence (Hoge, Smit, & Crist, 1997), social economic status (Jimerson, Egeland, & Teo, 1999), and school demographics (Sutton & Soderstrom, 1999). While this line of research has certainly shed light on how student personality and social factors can impact a child's education, the utility of this information is questionable if the goal of scientific inquiry is to improve scholastic prosperity. Most personality characteristics and social factors are relatively stable; very few introverts quickly turn into extroverts, and even fewer people increase their level of social economic status overnight. In contrast, the investigation of more mutable influences such as cognitive abilities may provide a promising direction for improving academic performance. The purpose of this work was to examine the impact of three cognitive factors on students' success in their science courses: reading skill, science knowledge, and knowledge of metacognitive reading strategies.

It is generally assumed that reading skill is a critical component of academic achievement. Skilled readers are more likely to monitor their comprehension and use active reading strategies such as previewing, predicting, making inferences, drawing from background knowledge, and

summarizing (Long, Oppy, & Seely, 1994; McNamara, 2001; Oakhill, 1984; Oakhill & Yuill, 1996). In addition, skilled readers tend to have more knowledge about the world – most likely from reading more often.

Readers' domain knowledge can have a dramatic impact on how well new information is acquired (Bransford & Johnson, 1972). For instance, many school texts are incomplete because they fail to make relations amongst concepts in the text explicit (Beck, McKeown & Gromoll, 1989). Accordingly, domain knowledge can facilitate comprehension by providing the reader with the necessary resources to fill in conceptual gaps (McNamara, Kintsch, Songer, & Kintsch, 1996). In addition, readers with greater prior knowledge are more likely to use effective reading strategies (Lundeberg, 1987) and convey greater interest in the reading material than low-knowledge readers (Tobias, 1994; Zhang, & Zhang, 1996). Collectively, these findings suggest that learners' prior knowledge critically determines their ability to learn and understand new information.

Metacognition refers to the ability to think about, understand and manage one's learning (Schraw & Dennison, 1994). In essence, metacognition is the capacity to monitor comprehension, and the initiative to correct misunderstanding. Recent research has revealed the significance of metacognitive awareness in learning. For instance, learners who score high on measures of metacognition are more strategic (Garner & Alexander, 1989), more likely to use problem-solving heuristics (Artzt & Armour-Thomas, 1992), better at predicting their test scores (Vadhan & Stander, 1994), and generally outperform learners who score low on metacognitive measures (Pressley & Ghatala, 1990).

More importantly, research has demonstrated the value of metacognition in predicting academic achievement. For example, greater metacognitive ability has been linked to grade point average (Everson & Tobias, 1998), math achievement (Maqsood, 1997), and reading skill (van Kraayenoord & Schneider, 1999). Moreover, McNamara and Scott (1999) demonstrated that providing metacognitive reading strategy training improved comprehension and course scores in college-level science courses.

The purpose of this investigation was to examine the influence of science knowledge, reading skill, and metacognitive reading strategies on high school students' achievement in science. While the individual effects of these factors on learning have been examined in separate studies, to the best of our knowledge, no single study has simultaneously measured the influence of all three variables

on students' comprehension and achievement in a classroom setting. Furthermore, we were interested in determining how course involvement, reading interest, and TV habits would influence science performance, and how well these variables would predict student success in comparison to the cognitive factors. Finally, we investigated whether reading skill or metacognitive reading strategies could compensate for knowledge deficits. In this study, science achievement was assessed by the student's science course grade, comprehension of a science passage, and a statewide measure of students' science achievement (Virginia's Standards of Learning, SOL). It was hypothesized that both the cognitive and student activity measures would reliably predict science achievement; but overall, it was hypothesized that the cognitive measures would better predict performance than measures of student activity.

In line with other work (Perfetti, 1989), it was hypothesized that either reading skill or metacognitive reading strategies would compensate for science knowledge. While some researchers have argued that reading skill and domain knowledge can compensate for each other (Perfetti, 1989), there is little consensus as to whether metacognitive reading strategies could make up for meager science knowledge. On the one hand, one might infer that high metacognitive reading strategies could help a learner offset a low level of science knowledge because research has shown that metacognition can compensate various cognitive abilities (Swanson, 1990). On the other hand, others have argued that metacognition has strong knowledge requirements; that is metacognition is not knowledge free (Schwartz & Bransford, 1998) and consequently, one might not expect metacognitive reading ability to compensate for low science knowledge. In any event, the issue is unclear and further investigation is required.

Method

Participants

The sample consisted of 1651 high school students from four schools. Four hundred and ninety-eight students were from an inner city high school in Norfolk, Virginia; 372 were from a rural high school in Americus, Georgia; 364 were from a rural Appalachian high school in Prestonsburg, Kentucky; and the remaining 417 were from a suburban high school in Williamsburg, Virginia. Students' grade level ranged from 9 to 12, and the average age of the students was 16.25 years.

Materials

Metacognitive reading strategy use was measured by a modified version of the Metacognitive Strategies Index (MSI) adapted for use with high-school students (Forget, 1999). The MSI is a 25-item multiple-choice questionnaire which is designed to measure six factors associated with metacognitive reading strategy use: predicting and verifying; previewing; purpose setting; self-questioning;

drawing from background knowledge; and summarizing. The Cronbach's Alpha for the MSI was $\alpha=.68$. Science knowledge was measured with an 18-item multiple choice test on general science information. The test consisted of questions concerning experimental methods, mathematics, and meteorology. Cronbach's Alpha for the science knowledge was $\alpha=.63$. Reading skill was measured by a modified version of the Gates-MacGinitie reading skill test for grades 10-12. The test consisted of 40 multiple choice questions designed to assess student comprehension on several short text passages. The reliability of the gates-MacGinitie is typically between $\alpha=.85-.92$ (Phillips, Norris, Osmond, & Maynard, 2002).

Students were given a questionnaire concerning their course involvement, reading interest and TV habits. The participants were required to rate the following statements related to their course involvement on a one to five-point scale: "How much do you enjoy learning science, or scientific concepts?"; "How much time per week do you generally spend reading and studying for this science course?" and "How much effort have you devoted to this science course?". For reading interest, the following questions were asked "How much do you enjoy reading?"; and "How many books do you read each year that are not required by your teachers?". TV habits were assessed by two questions: "How many hours of television do you watch during a school day?"; and "How many hours of television do you watch on the weekend?". The scales were designed such that higher numbers indicated larger amount of the entity in question.

Finally, participants were given an 844-word passage on meteorology (Flesch-Kincaid grade level of 6.7). The passage covered the types and origins of air masses as well as their impact on weather patterns. An accompanying set of 8 multiple choice and 12 open-ended comprehension questions were created for the passage. Cronbach's Alpha for the open ended questions was $\alpha=.72$, while alpha level for the multiple choice questions was $\alpha=.57$.

Design and Procedure

The students were tested during regular classroom hours in a 90-minute class period, or two 50-minute class periods, and all testing was conducted near the end of the academic year. The complete set of materials were presented in a single booklet with "stop" pages inserted between each measure. If a student finished a particular test early, they could recheck their answers, but could not go on to the next section. The participants completed the measures in the following order and time frame: Science passage and questions (20 minutes), Gates reading test (20 minutes), prior knowledge test (10 minutes) MSI (10 minutes), and the student activity questionnaire (5 minutes). At the end of the academic year, the students' science course grade and their Standards of Learning science scores were collected.

Results

The following results were significant at the $p < .001$ level unless noted otherwise. It was verified for all analyses reported here that students' age differences did not alter the pattern of results.

What's More Important?

A factor analysis was conducted to determine whether the predictors used in this study could be grouped into smaller subset of factors (e.g., Cognitive ability, reading interest, etc.). All 10 measures of student ability and activity were entered into the analysis using the principal components method of extraction. Predictors with Eigenvalues over 1 were retained in the analysis, and the Varimax procedure was used as the method of rotation. The analysis revealed four distinct factors that accounted for 68% of the overall variance. Science knowledge, reading skill and metacognitive reading ability loaded on factor 1, *Cognitive Ability* (loadings=.800, .760, .692; Eigenvalue=2.67), and accounted for 27% of the variance. The number of books read and reading enjoyment loaded on factor 2, *Reading Interest* (loadings=.891, .849; Eigenvalue=1.90), and accounted for 19% of the variance. The amount of TV watched on a school day and the amount watched on a weekend loaded on factor 3, *TV Habits*, (loadings=.890, .890; Eigenvalue=1.20) and explained 12% of the variance. Finally course effort, time spent reading and studying the textbook, and enjoyment of learning science loaded on factor 4, *Course Involvement* (loadings=.807, .684, .638; Eigenvalue=1.07), and explained 11% of the variance. Thus, the factor analysis provided support for our initial categorical distinction of the predictors.

The four factors were regressed onto each of the measures of science achievement. For the students' course grade, the overall model accounted for 13% of the variance, $F(4,1295)=49.57$. Reading interest did not predict course grade, whereas cognitive ability, $t(1295)=10.15$, $\beta=.263$, and course involvement $t(1295)=9.43$, $\beta=.244$ were strong predictors. TV habits significantly predicted course grade but the relationship was small $t(1295)=-2.43$, $\beta=-.063$, $p=.015$.

For students' SOL score, the overall model accounted for 38% of the variance, $F(4,618)=94.09$. Course involvement did not predict SOL scores, whereas cognitive ability, $t(618)=16.24$, $\beta=.516$, TV Habits, $t(618)=-9.23$, $\beta=-.294$, and reading interest $t(618)=5.06$, $\beta=.160$, were significant predictors.

Table 1 Correlations between science achievement and student activities.

Factor	Individual Measure	Course Grade	SOL	Open Ended Comp.	Multiple Choice Comp.
Cognitive Ability	Reading Skill	.24	.58	.64	.53
	Science Knowledge	.25	.59	.55	.51
	Metacognitive Reading Strat.	.20	.15	.26	.24
Course Involvement	Enjoy Learn Science	.18	.16	.13	.14
	Time Reading & Studying	.12	N.S.	N.S.	N.S.
	Effort Given to Course	.30	N.S.	N.S.	N.S.
Reading Interest	Number of Books Read	N.S.	N.S.	N.S.	.11
	Enjoyment of Reading	.12	.16	.14	.16
TV Habits	Hrs. TV School day	-.13	-.34	-.25	-.23
	Hrs. TV Weekend	N.S.	-.27	-.23	-.23

In terms of science passage comprehension scores, the model accounted for 42% of the variance for open-ended questions, $F(4,1213)=219.79$, and 33% for multiple-choice questions, $F(4,1292)=158.81$. For both comprehension measures, cognitive ability ($t(1213)=27.44$, $\beta=.600$; $t(1292)=22.56$, $\beta=.514$); reading interest ($t(1213)=5.01$, $\beta=.110$; $t(1292)=5.46$, $\beta=.124$); and TV habits ($t(1213)=-9.83$, $\beta=-.215$; $t(1292)=-9.58$, $\beta=-.218$) were significant predictors, whereas course involvement was not significant.

In summary, cognitive ability and TV habits were significant predictors for all of the student achievement measures. Course involvement reliably predicted only course grade, whereas reading interest reliably predicted SOL scores and science passage comprehension.

Table 1 presents the Pearson correlations between the students' science achievement performance (i.e., course grade, SOL, open-ended and multiple choice comprehension questions) and the 10 predictors used in this study. Correlations are significant at the $p < .001$ level unless specified otherwise. Several trends emerge from the analysis. First, the correlations between science achievement and the individual measures of cognitive ability are moderate to high. In contrast, the correlations between achievement and the individual measures of student activity were generally low. However, there were two exceptions, the amount of effort given to the course was moderately correlated with course grade ($r(1472)=.298$). In fact, of the measures used in this study, effort had the highest simple correlation with course grade. Second, the amount of TV watched on a school day and the weekend (with the exception of course grade) was moderately, but negatively correlated with science achievement. The magnitude of the correlations ranged from small for course grade ($r(1493)=-.125$ to moderate for SOL ($r(693)=-.337$).

Can You Compensate for Low Knowledge?

Our second question was whether either reading skill or metacognitive strategies would compensate for science knowledge. Hence, we conducted ANOVAs for each measure including science knowledge and reading skill in the first set, and science knowledge and metacognitive reading strategies in the second set. (The three variables could not be included in one analysis because there were cells with too few participants.) Students scoring in the top and bottom thirds for each cognitive ability measure were included in the analyses. The dependent variables included course grade, SOL score, open-ended questions, and multiple-choice performance.

Figure 1. Proportion of multiple-choice comprehension questions correct as a function of science knowledge and reading skill.

The first set of analyses, including science knowledge and reading skill, yielded significant effects for all of the dependent measures. The results were significant at $p < .001$ unless otherwise specified. There was a significant interaction of science knowledge and reading skill only for students' performance on the multiple-choice comprehension questions, $F(4,1368)=7.85$ (see Figure 1). This interaction indicates that neither science knowledge nor reading skill had a major impact on comprehension unless the student possessed both.

The second set of analyses, including science knowledge and metacognitive reading strategies, yielded significant effects of science knowledge for all of the dependent measures. Metacognitive strategies was significant for all of the measures except SOL. However, in this case, there was significant interaction of science knowledge and strategy use, $F(4,659)=2.52$, $p=.04$. As shown in Figure 2, greater metacognitive ability helped compensate for a student's low level of science knowledge. [No other interactions were significant.]

Figure 2. SOL score as a function of science knowledge and metacognitive reading strategy.

Discussion

One goal of the current investigation was to uncover some of the factors that are important in promoting high-school students' science achievement. A factor analysis of our ten measures of abilities and activities revealed that there were four distinct categories of variables: cognitive ability, TV Habits, reading interest, and course involvement. The results indicated that all four factors were important in predicting science achievement; however, some factors differentially predicted the measures of science achievement. Cognitive ability, and TV habits reliably predicted all measures of science achievement, while course involvement reliably predicted only course grade. In turn, reading interest predicted both SOL scores and passage comprehension.

A more detailed examination of the correlations between the individual components of the factors and science achievement revealed that all measures of cognitive ability and TV habits were relatively strong predictors of science achievement, while the individual measures of reading interest and course involvement were generally weak predictors. The major exception was the correlation between course effort and course grade, which proved to be the best single correlation with the students' grade.

The second goal of the study was to determine whether reading skill or metacognitive reading strategies could compensate for science knowledge (see also, Cottrell & McNamara, 2002). With multiple choice questions, science knowledge and reading skill interacted. In this case, neither science knowledge nor reading skill had a major impact on passage comprehension unless the learner had high levels of both cognitive abilities. This interaction is counter to the belief that reading skill and prior knowledge compensate for each other (e.g., Perfetti, 1989). If science knowledge and reading skill were compensatory, one would expect that a high level reading skill would make up for a low level

prior knowledge. Nevertheless, it is notable that the multiple-choice measure was the only dependent measure of science achievement for which an interaction occurred. In the other three cases (Sol score, open ended questions, and course grade), both reading skill and knowledge aided the students, and did not interact. So, in those cases, either reading skill or prior knowledge were beneficial – and thus could compensate for one another. Having both, of course, is the best scenario. Similarly, for the most part, either prior knowledge or metacognitive reading strategies were beneficial to students. In contrast, for SOL scores, metacognitive reading strategies and science knowledge interacted. High-knowledge students did not benefit from reading strategies. Yet, students with low science knowledge were presumably able to compensate for this knowledge deficit with reading strategies. The results support the notion that metacognitive reading strategies can compensate for a low level of domain knowledge.

So, what's a science student to do? The results of this study suggest several things. First, students should simply read more. Research has shown that an increase in exposure to print is associated with an increase in reading skill (see, McNamara, 2001). Accordingly, the current findings support the notion that reading skill is important for science achievement. In fact, reading skill was one of the best single correlates of student performance. Second, students should make informed decisions on the courses they take. For, example if a student is interested in taking biology courses, they should plan to take as many courses related to biology and chemistry in high school as possible. Prior knowledge is important in determining how well new information is learned. Thus the more elementary courses one has in a domain, the easier it will be to learn more advanced courses in the same domain.

However, as we well know, students will often find themselves in courses for which they are ill prepared. In that case, knowing and using metacognitive reading strategies can help the learner to partially overcome knowledge deficits. Hence, the results of this study suggest that students should increase their metacognitive awareness. Unfortunately, students do not automatically engage in such processing (Garner, 1990). Consequently, the solution is to discover and implement techniques that promote metacognitive strategy use (e.g., McNamara & Scott, 1999).

Finally, our findings suggest that parents and students should find a healthy balance between the amount of TV watched and the amount of effort the student puts into the course. Of the measures of student activity, TV habits seemed to be one of the best predictors of science performance: TV viewing was reliably related to all four of our measures of science achievement. However, the relationship between TV viewing and science achievement was negative. This result is congruent with research on TV viewing, which suggests that TV viewing can have a negative impact on reading comprehension (e.g., Koolstra, van der Voort, & van der Kamp, 1997). Conversely, our results underscore the importance of student effort on course performance; students' effort was the best single correlate of course performance. While readers often prefer

the path of least resistance (McNamara et al., 1996) it is important to encourage students to expend effort into their academic endeavors.

It is important to note that these results were based on correlation, and therefore should be interpreted with caution. Despite this limitation, the conclusion we draw from this work is that both cognitive ability and student activities are important for science achievement. Moreover, it is important to develop ways to promote reading, and interest in reading, as well as ways to increase course involvement. These findings also recommend that parents should play an active role in educating children to balance their TV viewing and academic endeavors. Finally, the results suggest the need for the development and implementation of strategies to promote metacognitive awareness.

Acknowledgements

We would like to thank the members of the ODU Strategy Lab who helped to conduct this study, including Kim Cottrell, Meghan Depont, Karen Fuller, Erin McSherry, Raymond Morgan, Grant Sinclair, Danny Simmons, Karen Stockstill, and Paul Walker. This project was supported by an NSF IERI grant (REC-0089271) to the second author. Both authors can be contacted at the University of Memphis.

Is there evidence for unconscious reasoning processes?

Magda Osman (M.Osman@ucl.ac.uk)

Department of Psychology, University College London,
Gower Street, London, WC1E 6BT, UK

Abstract

Current theories of reasoning propose that reasoning is governed by two systems: conscious and unconscious. Conscious processing directs analytical thinking and results in correct responding, while unconscious processing employs heuristics that often leads to poor performance in deductive reasoning tasks. The present study uses a classic propositional task to examine the properties that distinguish conscious from unconscious reasoning. Overall, the study did not find support for dissociable reasoning systems. Instead, the findings suggest that the features exclusively attributed to each system, by dual reasoning theorists, were equally applicable to both.

Dual Process Theories

At present there are three theories of reasoning that have divided the process into unconscious and conscious components: Evans and Over's (1996) Dual process theory; Sloman's (1966) Two systems theory and Stanovich and West's (2000) Two systems theory. Stanovich and West (1998) present a summary of the general attributes that distinguish conscious from unconscious reasoning processes. They propose that unconscious processes are inaccessible, automatic, inert, non-declarative, and non-verbalizable, while conscious processes are accessible, controllable, declarative, and verbalizable. The different characteristics also imply that the two reasoning systems serve different purposes, result in different responses, and encode information differently. Many studies developed to investigate the different systems originate from Wason's (1966) conditional reasoning task. One reason for this is that the general errors individuals make when solving this task have been the impetus for attributing unconscious mechanisms to reasoning. The aim of the present study is to examine the dual processes theories characterization of deductive reasoning using Wason's (1966) conditional reasoning task.

Wason (1966) developed a task (hereafter Wason's selection task) that has now become the mainstay of studies investigating deductive reasoning. It involves a conditional statement: if there is a vowel on one side of the card, then there is an even number on the other side. Participants are told that they have to discover

whether the statement is true by selecting cards to turn over from an array of four (e.g., E, K, 2, and 5), which are represented in logical notation as (P, 'P, Q, 'Q). The correct solution requires the selection of the E (P) and 5 ('Q) cards, because only this combination provides a means of confirming and falsifying the statement. Typically, only a small proportion of participants solve the task correctly (e.g., 5-10%), while most choose a range of alternative card combinations, the most popular of which is E (P) and 4 (Q).

The appeal of this task comes from the robust results it generates, in particular the regularity with which E and 4 cards are selected. The matching bias theory proposed by Evans (1972) and Evans and Lynch (1973) is the most accepted explanation of this phenomenon. They propose that instead of triggering reasoning processes the selection task incites participants to simply match their card choices with those named in the statement. Evans (1972) developed a paradigm to examine this by presenting participants negated versions of the statement. He found that participants still selected P and Q cards irrespective of the presence of negations in the statement, thus leading to the conclusion that the selection task is solved using simple heuristics. A more detailed account proposed by Wason and Evans (1975) explains the underlying processes that motivate matching behavior. They suggested that reasoning is comprised of two dissociated processes, one of which is unconscious and based on quick-fix strategies that are guided by particular preferences for a response (i.e., biases). The second process is conscious and rationalizes behavior, some of which the reasoner has little control over. These proposals were based on findings from protocols studies (Evans & Wason, 1976; Wason & Evans, 1975), which required participants to provide justifications for their card selections. Participants showed a lack of awareness of the actual processes involved in selecting cards, and rationalizations of their behavior were found to be independent of their actual card selections.

Following from Wason and Evans protocol studies, a variety of techniques have been developed to uncover unconscious reasoning processes e.g., transfer tasks (e.g., Berry, 1983), and attentional biases (Evans, 1996; Evans, Ball & Brooks, 1987; Roberts, 1997; Roberts & Newton, 2001).

The findings from some of these designs suggest that the characteristics attributed exclusively to one or other of the two types of reasoning process are inaccurate. For instance, Berry (1983) reported that participants possessed insight into the processes motivating their card selections, and that this knowledge contributed to transfer of correct responding across different versions of the selection task. This conflicts with the proposal that individuals lack awareness of the processes that contribute to solving the selection task, and that protocols are actually post hoc rationalizations of card choices (Evans and Wason, 1975).

The Present Study

The objective of this study is to examine three of the claims made by the dual process theories of reasoning.

Evans, Ball and Brooks (1987) measured the order in which cards were selected and rejected; they found that decisions were made earlier for card selections than rejections. They proposed that the reasons for this are the result of unconscious biases that motivate participants to focus their attention on cards that match those named in the statement. However, attentional bias has been inferred from measures of decision making/card selecting behavior. There have been a number of studies that have investigated aspects related to attentional bias (e.g., Evans, 1996; Evans, Ball & Brooks, 1987; Dominowski, 1995; Roberts, 1998; Roberts & Newton, 2001), and in general the findings are mixed. One of the objectives of this study is to examine the prediction that attention is first directed to cards that are selected first. Furthermore, there has been no direct attempt to try and separate out attentional processes from decision making processes, and the present study attempts to remedy this.

The three dual process theories characterize unconscious processing as inflexible, and this property has been used to account for the poor rate of correct responding following tutoring on conditional reasoning (e.g., Wason & Johnson-Laird, 1970; Wason & Shapiro, 1971). The present study investigates this effect by including a tutoring session in the experiment and measuring the extent to which performance is improvement in subsequent versions of the selection task.

Stanovich and West (2000) describe the emergence of individual differences within the two reasoning systems. They suggest that matched card selections are motivated by the same unconscious bias, which also implies that unconscious processes are ubiquitous and not subject to variation. By contrast, individual differences occur during conscious processing because participants have overcome the tendency to select matched cards, and have based their card choices from their own construal of the statement, which in turn

results in a variety of construals and therefore card combinations. However, this is a rather circular argument, since evidence of individual differences is supported by the view that they only emerge during conscious processing, and similarly, conscious processing is identified by the selection of cards that are not matched to the rule. This study examines the occurrence of individual differences in card selecting behavior during different conditions.

Method

The present study combines a series of methods designed to examine unconscious reasoning that have not been used in combination in previous studies of the selection task. Three techniques in particular have been adapted for the purposes of this study.

Roberts and Newton (2001) developed a rapid response task (hereafter RRT) that limited conscious analytic processing in order to encourage automatic responding in the selection task. During this task participants were shown the example cards for 1 second, and asked to respond yes or no depending on whether they would select the card or not. In the present study participants were asked to study a statement, which based on the typical presentation of the conditional statement in standard versions of the selection task. Then, participants were exposed to the four cards A K 4 and 7 serially, for 90 msec. They were then asked to decide after each card presentation whether they would select the card or not, and told to respond as quickly as possible. Participants were also asked to rate how confident they were of their decision on a 1-7 point scale (1 not confident, and 7 highly confident). One problem that has pervaded this type of design is that while participants are looking at the cards they are also considering their selection, so it is hard to infer attentional biases when the measure might be contaminated by decision making processes as well (Roberts, 1997). It should be noted that the present study does not claim that the method elicits unconscious processing, only that it encourages attentional biases, and attempts to separate them from decision making processes.

This study also includes a tutoring session and uses some of the techniques developed by Green and Larking (1995). In the present study participants were asked to imagine what were the possible outcomes on the underside of each of the four cards when they turned them over. Participants were also asked to suggest what implications the outcomes would have for the conditional statement. After this, the experimenter explained the concept of material implicature and the necessity of falsification in order to solve the selection task correctly.

A generation task was used to measure the extent to which participants understood the concepts they were introduced to during the tutoring session. This design was originally used by van Duyne (1976) and later incorporated into a study by Legrenzi (1980). The general format of this task uses a conditional statement but no given premises (e.g., if ____, then ____), and participants are required to generate their own statement, devise the examples, and then test the statement.

Participants

Forty-eight graduate and undergraduate students from Brunel University took part in the experiment. Each participant was screened for prior knowledge of the selection task. They were assigned randomly to one of the 48 possible permutations of the four cards presentations in the RRTs.

Procedure

In the present study each participant completed the six tasks, all of which were variations of the standard abstract selection task. Participants were required to solve the tasks in the same order starting with the first RRT (Task 1), 3 versions of the abstract selection task presented in a booklet (Tasks 2-4), followed by a tutoring session, a second RRT (Task 5), and finally, the generation task (Task 6). The instructions in the second RRT task were identical to the first with exception of the actual letters and numbers, and the order in which they were presented for each participant.

Results

Card Selections

Table 1 reports the frequencies of all the cards combinations selected in each of the six tasks. A log-linear analysis was favored over Pearson's chi-squared in order to determine statistical regularities in the data.

The following analyses of card selecting behavior across tasks are based on a collapsed version of Table 1. This included separate frequencies for the main card selections [P, P Q, P ~Q, Q, P Q ~Q], while the remaining figures were classed as residuals. Significant differences were found between the frequencies of card combinations selected in the six tasks, $G^2 = 180.320$ (25), $p < .0001$. On closer inspection there were no significant differences between cards selected in the three tasks presented in the booklet (Tasks 2-4), G^2 (8) = 7.960, $p > .43$, which suggests that the source of difference was based specifically on responses to the RRTs and the generation task.

Table 1: Frequencies of card selections for each of the six tasks

	Task 1	Task 2	Task 3	Task 4	Task 5	Task 6
P	12	4	3	5	14	4
PQ	17	34	37	37	6	8
P~P	1	0	1	0	2	2
P~Q	0	1	0	1	13	17
~P	4	1	0	0	0	0
~P~Q	1	0	2	2	0	1
~PQ	0	0	0	0	2	0
P~PQ~	2	1	0	0	0	1
Q						
P~PQ	2	0	0	0	2	1
PQ~Q	2	0	0	0	6	11
P~P~Q	2	0	0	0	1	2
Q	2	7	4	3	0	0
~Q	0	0	1	0	0	0
Q~Q	3	0	0	0	2	1

Participants' card selections in both RRTs were compared, this revealed a highly significant difference between the two tasks, G^2 (12) = 32.28, $p < .001$. A comparison between the frequency of cards selected in the second RRT, and the proceeding generation task revealed no significant difference, G^2 (4) = 8.257, $p > .08$. Thus, the responses to both tasks presented after tutoring were not statistically different. A further analysis between card choices for the first RRT and its proceeding task (the first booklet task) showed there was a highly significant difference, G^2 (5) = 28.315, $p < .0005$.

Analyzing correct card choices across the six task revealed that significantly more correct responses were made in tasks after the tutoring session, than preceding it, G^2 (5) = 63.013, $p < .0001$, thus suggesting that tutoring facilitated correct responding.

Decision Latencies

The mean decision times for card selections and rejections between the two RRTs were compared. This analysis showed there was no significant difference, G^2 (1) = 0.354, $p > .55$. An analysis based only on decision times of participants choosing the P and Q cards in both RRTs was conducted, a summary of the mean decision times for card selections and rejections is presented in Table 2.

Table 2: Mean decision times for cards selected (PQ) and rejected ('P'Q) in RRT 1 and RRT 2

	RRT 1	RRT 2
Card selections	10051.50 msec	8999.83 msec
Card rejections	9665.59 msec	8877.94 msec

There was no significant difference between decision times for rejected and selected cards, $G^2(1) = 1.513$, $p > .21$. A further analysis was carried out on responses to individual cards. A 2 (response type: selection vs. rejection) \times 4 (card type: P, 'P, Q, 'Q) analysis of variance (ANOVA) revealed no significant main effect for response type in the first RRT1, $F(1, 46) = .003$, $MSE = 61776.125$, $p > .95$, and the same was found for RRT2, $F(1, 46) = 1.302$, $MSE = 28899003$, $p > .337$. There was also no significant main effect for card type for RRT1, $F(3, 138) = .803$, $MSE = 91337103$, $p > .504$, and RRT2, $F(3, 138) = .817$, $MSE = 7774520$, $p > .506$. Finally, there was no significant interaction between response types and card type for either tasks, RRT1 $F(3, 138) = 1.538$, $MSE = 14650821$, $p > .230$, and RRT2 $F(3, 138) = 1.928$, $MSE = 19278503$, $p > .196$. These findings suggest that there is no difference between the decision times for cards selected and rejected and does not support Evans, Ball and Brooks (1987) claim that participants make earlier decisions for cards they select.

Along with measurements of decision times, confidence ratings for each decision made were recorded. The overall ratings were not significantly different across both tasks, $G^2(42) = 48.043$, $p > .24$, further analyses were carried out comparing both RRTs based on ratings for individual cards. There was no significant difference between the ratings for the P card, $G^2(6) = 5.218$, $p > .5$; 'P card, $G^2(6) = 4.065$, $p > .5$; and the 'Q card, $G^2(6) = 3.112$, $p > .5$. However participants responded with higher confidence ratings for the Q card in the second RRT compared to the first RRT, and this was statistically significant, $G^2(6) = 15.929$, $p < .01$.

Analyses of confidence ratings between RRTs and within each RRT, for both rejected and selected cards, revealed significant differences only for the Q card. Participants were significantly more confident when deciding to select the Q card, $G^2(6) = 15.209$, $p < .01$, and to reject it, $G^2(6) = 13.055$, $p < .05$ in the second RRT which proceeded tutoring. In the selection task literature the Q card has been thought to generate misunderstandings, which may account for the significant results found for confidence and latency measures based on this card.

Tutoring

During the tutoring sessions participants were asked to consider the possible outcomes (i.e., true, false) for the statement based on information represented on the underside of each card. This technique was used to gauge participants initial understandings of the statement and cards.

All the participants assessed the statement correctly according to the outcomes of information represented on the underside of the P card. The majority of participants reported that each outcome from turning the 'P card was irrelevant and had no consequences for the statement, which is an incorrect assumption. With the exception of one, the remainder believed that turning the Q card to reveal a P would imply that the statement was true, which is also a commonly held misconception. Approximately half correctly assumed that discovering a P on the underside of the 'Q card would suggest the statement was false.

In sum, participants have a correct understanding of the P card, and they also appreciate that the 'Q card can falsify the statement, but misunderstand its relevance, evidenced in its absence from most participants card choices prior to tutoring. The Q card was the most misunderstood, and directly related to participants difficulty in appreciating that a bi-conditional interpretation (e.g., if and only if there is a vowel, then there is an even number, which also implies that if there is an even number, then there is a vowel) could not be assumed for the conditional statement.

The data from the tutoring sessions also suggest that participants misunderstandings of the cards did not correspond to previous responses in the booklet (Tasks 2-4). To illustrate, approximately 75% of participants selected the PQ card combination in the booklet, the corresponding misconception entails assuming that turning a Q card and discovering a P would also verify the statement, and that turning the same card over to reveal a 'P would in turn suggest the statement was false. However, comparing participants prior card selections revealed that they displayed a variety of misconceptions, and there was no significant relationship between particular card choices (i.e., P and Q) and its corresponding misinterpretation.

Discussion

The present study investigated unconscious deductive processes based on the claims made by the three theories, and the findings strongly imply that the characterisation of unconscious processes is inaccurate. The findings also challenge the extent to which unconscious and conscious processes can be considered as dissociated. However, it could be argued that the present study did not adequately demonstrate unconscious reasoning processes, and this is the reason

why the claims were not supported. Certainly there is some doubt over what the methods used presently actually demonstrate, but it was thought that the most appropriate method of examining the proposals of dual process theories was to use similar types of task designs, the findings of which the theories have used to support their claims.

Card Selections in the Rapid Response Tasks

The RRT tasks were designed to separate out attentional processes from decision making processes. Thus, the brief exposure of the cards did not allow participants to think about selecting cards while viewing them. The less restricted interval for choosing enabled participants to reflect on their choices under some degree of uncertainty as to what cards they saw.

The analyses suggested that participants differed in their card selections during RRTs. If unconscious processes are inflexible, then there should be a correspondence between the cards selected in both RRTs, and tutoring should have no effect, however this was not found in the present study. Instead, the findings suggest that tutoring influenced reasoning processes employed in restricted as well as in free time tasks, implying that unconscious processes are not inflexible.

Comparisons between card choices in the first RRT and its proceeding task, which was a free time version presented in the booklet, revealed significant differences. Furthermore, 17/48 participants selected matched card selections under restricted time conditions, compared to 34/48 in the first booklet task. If matched card selections are indicative of unconscious reasoning processes then the proportion of matched card selections should be the same for both tasks. 17/48 participants selected the same card combinations in the first RRT and the first booklet task, (compared with 24/48 consistent card selections between the second RRT and the generation task), however, 13/17 participants selected matched cards in these tasks. While the later result lends some support to dual process theorists' view of matched card selections, the other findings reported here provide a stronger case against their proposals.

Decision Latencies

Attentional bias has been proposed as an explanation for the longer latencies found for cards selected than rejected in inspection time studies (e.g., Evans, 1996; Evans, Ball, & Brook, 1987). The present findings suggest that participants' decision times were not markedly different for different types of card selecting decisions. There were, however, differences between overall responses latencies in the RRTs. Participants made quicker decisions during the second RRT compared to the first. The tutoring participants received before the second RRT may have influenced this result,

because they were better informed about the task requirements. Furthermore, there were no differences between the two RRTs based on confidence ratings. However, the only significant difference was found for ratings of the Q card, participants were more confident of their decisions during the second RRT compared to the first. One reason for this may have been the tutoring received prior to the second RRT, suggesting that an increase in understanding also results in an increase in confidence.

Tutoring

There have been many examples of unsuccessful attempts to tutor participants on conditional reasoning (e.g., Wason, 1968; Wason & Johnson-Laird, 1970; Wason & Shapiro, 1971). Wason (1968) first introduced remedial procedures or 'therapies' to invoke insight into the task. Johnson-Laird and Wason (1970) proposed that participants failed to solve the task correctly because there was a disassociation between participants' selection and evaluation processes. Wason and Johnson-Laird (1970) suggested that selecting is an active process and occurs immediately before evaluation because the evaluation process is effortful and more cognitively demanding.

The lack of transfer reported in tutoring studies has been used to demonstrate dissociations between conscious and unconscious reasoning processes. Participants' inability to adopt new concepts, taken together with the fact that they revert to previous card choices, typically P and Q, suggest that either the methods of tutoring are inadequate, or the processes guiding card selections in the abstract task are inflexible. The results from the present experiment challenge both views.

A reduction in the proportion of matched card choices (i.e., P Q) following tutoring, and an increase in correct card selections (i.e., P~Q) suggest that tutoring was effective, and that participants' reasoning processes are not inflexible. Also, individual differences were revealed in the tutoring session, indicating that participants held a variety of misconceptions of the statement and the cards, which were corrected following tutoring. Moreover, many participants did not share the same misconceptions despite having selected the same card combinations in previous tasks. Thus, the selection of P and Q cards does not imply that participants have the same understanding of the cards, or that they are employing the same underlying reasoning process.

Conclusions

The findings from this study do not support the claims made by dual process theories of reasoning. However, it is not possible to rule out the possibility that

unconscious processes are involved in reasoning. This cautionary approach is based on problems concerning methodology. The techniques used to expose unconscious reasoning processes are not sufficiently refined to decide whether the description of the processes is inaccurate and that unconscious processes are still present, or whether there are actually no unconscious processes in reasoning.

A Unified Model Of The Origins Of Phonemically Coded Syllable Systems

Pierre-yves Oudeyer
Sony Computer Science Lab, Paris
e-mail : py@csl.sony.fr

Abstract

Human sound systems are invariably phonemically coded, which means that there are parts of syllables that are re-used in other syllables. It is one of the most primitive compositional system in language. To explain this phenomenon, there existed so far three kinds of approaches : "Chomskyan"/cognitive innatism, morpho-perceptual innatism and the more recent approach of "language as a complex cultural system which adapts under the pressure of efficient communication". We proposed in (Oudeyer 2002) a new hypothesis based on a low-level model of sensory-motor interactions, characterized by the absence of functional pressure and the use of very generic neural devices. This paper presents a unified model of the origins of syllable systems which does allow a comparison of the different hypothesis on the same ground. We show that our hypothesis is the only one to be sufficient, and that all others are not necessary. Moreover, the model we present the first that shows how a population of agents can build culturally a complex sound systems without the assumption that they already share a phonemic repertoire.

What does explain phonemically coded syllable systems ?

Human sound systems have very particular properties. Perhaps the most basic is that they are phonemically coded. This means that syllables are composed of re-usable parts. These are called phonemes. Thus, syllables of a language may look rather like la, li, na, ni, bla, bli, etc ... than like la, ze, fri, won, etc This might seem unavoidable for us who have a phonetic writing alphabet, but in fact our vocal tract allows to produce syllable systems in which each syllable is holistically coded and has no parts which is also used in another syllable. Yet, as opposed to writing systems for which there exists both "phonetic" coding and holistic/pictographic coding (for e.g. Chinese), all human languages are invariably phonemically coded.

The question is then : Why is this so ? How did it appear ? What are the genetic, glosso-genetic/cultural, and ontogenetic components of this formation process ? These questions are of particular interest and generality since phonemic coding is a

form of primitive compositionality. Compositionality is thought to be the keystone of syntax, and thus understanding how it appeared might help a lot to understand syntactic languages which make humans unique. Several approaches have already been proposed in the literature.

The first one, known as the "post-structuralist" Chomskian view, defends the idea that our genome contains some sort of program which is supposed to grow a language specific neural device (the so-called Language Acquisition Device) which knows a priori all the algebraic structures of language. This concerns all aspects of language, ranging from syntax to phonetics (Chomsky and Halle, 1968). In particular this neural device is supposed to know that syllables are composed of phonemes which are made up by the combination of a few binary features like the nasality or the roundedness. Learning a particular language only amounts to the tuning of a few parameters like the on or off state of these features. It is important to note that in this approach, the innate knowledge is completely cognitive, and no reference to morpho-perceptual properties of the human articulatory and perceptual apparatuses appears. This view is becoming more and more incompatible with neuro-biological findings (which have basically failed to find a LAD), and genetics/embryology which tend to show that the genome can not contain specific and detailed information for the growth of so complex neural devices.

Another approach is that of "morpho-perceptual" innatists. They argue (Stevens 1972) that the properties of human articulatory and perceptual systems explain totally the properties of sound systems. More precisely, their theory relies on the fact that the mapping between the articulatory space and the acoustic and then perceptual spaces is highly non-linear : there are a number of "plateaus" separated by sharp boundaries. Each plateau is supposed to naturally define a category. Hence in this view, phonemic coding and phoneme inventories are direct consequences of the physical properties of the body. Yet, it seems that there are flaws to this view : first of all, it gives a poor account of the great diversity that characterize human languages. All humans have approximately the same articu-

latory/perceptual mapping, and yet different language communities use different systems of categories. One could imagine that it is because some "plateaus"/natural categories are just left unused in certain languages, but perceptual experiments (Kuhl 2000) have shown that very often there are sharp perceptual non-linearities in some part of the sound space for people speaking language L1, corresponding to boundaries in their category system, which are not perceived at all by people speaking another language L2. This means for instance that Japanese speakers cannot hear the difference between the "l" in "lead" and the "r" in "read". As a consequence, it seems that there are no natural categories. This paper will provide quantitative evidence that the morpho-perceptual innatism hypothesis is not a satisfying candidate.

A more recent approach proposes that the phenomena we are interested in come from self-organization processes under functional pressures occurring mainly at the cultural and ontogenetic scale. The basic idea is that sound systems are good solutions to the problem of finding an efficient communicative system given articulatory, perceptual and cognitive constraints. And good solutions are characterized by the regularities that we try to explain, in particular phonemic coding. This approach was initially defended by (Lindblom 1992) who showed for example that if one optimizes the energy of vowel systems as defined by a compromise between articulatory cost and perceptual distinctiveness, one finds systems which are phonemically coded which means that some targets composing syllables are re-used (note that Lindblom presupposes that syllables are sequences of targets, which we will do also in this paper). Yet, these results were obtained with very low-dimensional and discrete spaces, and it remains to be seen if they remain valid when one deals with realistic spaces.

These experiments were a breakthrough as compared to innatist theories, but provide unsatisfying hypothetical explanations : indeed, they rely on explicit optimization procedures, which never occur as such in nature. There are no little scientists in the head of humans which make calculations to find out which vowel system is cheaper. Rather, natural processes adapt and self-organize. Thus, Lindblom's model does not really provide explanations, and one has to find the processes which formed these sound systems, and can be viewed only a posteriori as optimizations. This has been done for the questions of vowel inventories regularities : indeed, in spite of the fact that our vocal tract allows us to produce thousands of different vowels, languages of the world use rarely more than 10 of them, and most often 5 of them. Moreover, among these actually used vowels, some of them appear very often (e.g. [a], [i] or [u] in 89 percent of languages) and others are very rare (e.g. [y]). Lindblom proposed

a model which again optimized motor and perceptual constraints, which predicted these regularities. (de Boer 2001) developed an explanatory model in which the basic processes which do produce realistic vowel systems are imitation behaviors among humans/agents. He built a computational model which consisted of a society of agents playing culturally the so-called "imitation game". Agents were given a physical model of the vocal tract, a model of the cochlea, and a simple prototype based cognitive memory. (Oudeyer 2001b) extended this model by letting agents produce complex utterances (syllables), and showed how realistic phonotactic regularities (e.g. the sonority hierarchy principle, the high occurrence of CV syllables, etc...) could emerge without being explicitly programmed in. Yet, as far as phonemic coding is concerned, which is the focus of interest in this paper, (Oudeyer 2001b) does not provide explanations : possible phonemes that agents can use were pre-given and phonemic coding were pre-programmed. There is clearly a need to extend this model by not giving initially a limited and discrete set of possible phonemes and by not coding in phonemic coding. This is what we are going to present in this paper. Interestingly, the solution will rely on a model by (Oudeyer 2002) which was initially developed to explore the last hypothesis of phonemic coding.

Indeed, (Oudeyer 2002) is so far the only truly explanatory model for the phenomenon of phonemic coding. The hypothesis it proposes is that phonemic coding might be a non-functional consequence of sensory-motor coupling. "Non-functional" means that as opposed to models presented in last paragraph, there is no pressure of efficient communication. Phonemic coding, which is indeed useful to develop efficient communication system, yet would not have appeared for this task but may have been recruited only afterwards, being available "by chance" : this kind of phenomenon is sometimes called "exaptationism". The model is at a lower-level than others since it uses neural cortical maps, and their dynamics, coupling perception and action, provides one explanation for phonemic coding. (Oudeyer 2002) explained that this model was not incompatible with functional models such as (de Boer 2000, Oudeyer 2001b), but rather could be a possible manner to bootstrap imitation games. This is what we are going to show in this paper by integrating (Oudeyer 2001b) and (Oudeyer 2002). A problem appeared in previous research when one tried to have agents play imitation games with complex utterances : there were two levels, i.e. the level of articulatory targets/phonemes, and the level of syllables (sequences of phonemes). With simple binary feedback signal, it was difficult to know what kind of errors one agents may have done : wrong number of phonemes ? right number but one is badly imitated ? one phoneme is unknown ? or

is this the new complex sound which is unknown? In the model presented here, these problems disappear since the low level of targets/phonemes works without supervision. Finally, the model is flexible enough to allow an implementation of all the non-cognitive innatist hypothesis: morpho-perceptual innatism, functionalism of Lindblom, and exaptationism of Oudeyer.

We will first present an overview of the model in (Oudeyer 2002), then extend it so as to unify it with (Oudeyer 2001b), and finally show how the tuning of some parameters allows to instantiate the various hypothesis concerning the origins of phonemic coding. Then we will present results evaluating each hypothesis.

The coupled neural maps model

The model is based on topological neural maps. This type of neural network has been widely used for many models of cortical maps (Morasso et al., 1998). It relies on two neuroscientific findings (Georgopoulos 1988): on the one hand, for each neuron/receptive field in the map there exist a stimulus vector to which it responds maximally (and the response decreases when stimuli get further from this vector); on the other hand, from the set of activities of all neurons at a given moment one can predict the perceived stimulus or the motor output, by computing what is termed the population vector (see Georgopoulos 1988): it is the sum of all preferred vectors of the neurons ponderated by their activity. When there are many neurons and the preferred vectors are uniformly spread across the space, the population vector corresponds accurately to the stimulus that gave rise to the activities of neurons, while when the distribution is inhomogeneous, some imprecisions appear. (Oudeyer 2001a) showed that this imprecision allows to explain the well-known phenomenon of "perceptual magnet effect" (Kuhl 2000), which is a perceptual warping of the acoustic space. Moreover, the neural maps are recurrent, and their relaxation consists in iterating the coding/decoding with the population vector: the imprecision coupled with positive feedback loop forming neuron clusters provides well-defined non-trivial attractors which can be interpreted as (phonemic) categories.

There are two neural maps: one articulatory which represents the motor space, and one acoustic which represent the perceptual space. The two maps are fully connected to each other with symmetric weights. These weights are supposed to represent the correlation of activity between neurons, and allow to perform the double direction acoustic/articulatory mapping. They are learnt with a hebbian learning rule.

The network is initially made by initializing the preferred vectors of neurons to random vectors following a uniform distribution. Part of the initial state can be visualized by plotting all the preferred

vectors as in one of the upper squares of figure 1 which represents the acoustic maps of two agents (the perceptual space is 2-dimensional, and points represents the preferred vectors of neurons). One can also visualize the initial attractors of the acoustic neural maps: the lower squares of figure 1 show examples, in which each arrow has its ending point being the population coded vector after one iteration of the relaxation rule with initial activation of neurons corresponding to the population vector represented as the beginning of the arrow. What one can notice is that initially, attractors are few, trivial and random (most often there is only one).

Then there is a learning mechanism used to update the weights/preferred vectors in the two neural maps when one agent hears a sound stimulus which is represented by a temporal sequence of feature vectors, typically corresponding to the formants of the sound at a moment t (formants are the frequencies for which there is a peak in the power spectrum). For each of these feature vectors, the activation of the neurons in the acoustic map is computed, which propagates to the motor map. Then, each neuron of each map is updated so as to be a little bit more responsive to the perceived input next time it will occur (which means that their preferred vectors are shifted towards the perceived vectors).

The agents in this model produce dynamic articulations. These are generated by choosing N articulatory targets, and then using a control mechanism which drives the articulators successively to these targets. In the experiments presented here, $N=3$ for sake of simplicity. The choice of the articulatory targets is made by activating successively and randomly 3 neurons of the articulatory map. Their preferred vectors code for the articulatory configuration of the target. Finally, gaussian noise is introduced just before sending the target values to the control system. By default, the variance of the gaussian equals 5 percent of the extent of each articulatory dimension.

When an articulation is performed, a model of the vocal tract is used to compute the corresponding acoustic trajectory. There are two models. The first one is abstract and serves as a test model to see which properties are due to the particular shape of the articulatory/acoustic mapping and which are not. This is simply a random linear mapping between the articulatory space and the acoustic space.

The second model is realistic in the sense that it reproduces the human articulatory to perceptual mapping concerning the production of vowels. We model only vowels here for sake of computational efficiency. The three major vowel articulatory parameters are used: (Ladefoged and Maddieson, 1996) tongue height, tongue position and lip rounding. To produce the acoustic output of an articulatory configuration, a simple model of the vocal tract was used, as described in (de Boer, 2000), which generates the first and second effective formants which are

known to represent well human perception of vowels (de Boer, 2000). This model does not allow to deal with consonants, but is enough to investigate at least the phonemic coding of vowel targets.

The experiment presented consists in having a population of agents (typically 20 agents) who are going to interact through the production and perception of sounds. They are endowed with the neural system and one of the articulatory synthesizers described previously. They interact by pairs of two : at each round, one agent is chosen randomly and produces a dynamic articulation according to its articulatory neural map as described earlier. This produces a sound. Then another random agent is chosen, perceives the sound, and updates its neural map with the learning rule described earlier.

Let us describe first what we obtain when agents use the abstract articulator. Initially, as the receptive fields of neurons are randomly and uniformly distributed across the space, the different targets that compose the productions of agents are also randomly and uniformly distributed. What is very interesting, is that this initial state situation is not stable : rapidly, agents get in a situation like on figures 2 which corresponds to figures 1 after 1000 interactions in a population of 20 agents. These shows that the distribution of receptive fields is not anymore uniform but clustered. The associated point attractors are now several, very well-defined, and non-trivial. Moreover, the receptive fields distribution and attractors are approximately the same for all agents. This means that now the targets that agents use belong to one of well-defined clusters, and moreover can be classified automatically as such by the relaxation of the network. In brief, agents produce phonemically coded sounds. The code is the same for all agents at the end of a simulation, but different across simulations due to the inherent stochasticity of the process.

Now, (Oudeyer 2002) showed that when you use the realistic articulatory synthesizer, you get additionally vowel systems (defined as the set of point attractors) which do follow very well the tendencies observed in human languages. As a consequence, this model proposes and show the plausibility of the hypothesis : phonemic coding and the existence of shared categorical systems might be a result of the dynamic properties of very generic neural tissues (the same maps can be used for hand-eye coordination for instance), but which particular categories appear is due to the particular shape of the articulatory to perceptual mapping (but this alone is not necessary for phonemic coding, and we will argue here that it is also not sufficient).

Figure 1: Acoustic 2-D neural maps at the beginning (top), and associated population vector function (bottom) for two agents

Integration within a functional model of the origins of syllable systems

In the coupled neural maps model, there was no shared repertoire of complex sound categorization which was constructed. Obviously, when one agent would hear a complex utterance, the perceptual trajectory would go through zones of the space each belonging to the basin of attraction of a category. But this does not allow to decode appropriately for instance complex utterances made of articulatory targets whose basins of attractions are not connex : the interpolation taking place during the actual articulation will lead to articulatory and perceptual trajectory who go through basins of attraction of categories which do not correspond to any of the initial targets. As a consequence, if one wants to have a model of the origins of syllable systems, it is necessary to add another mechanism. Here this mechanism will be just the one described in (Oudeyer 2001b), and as opposed to the coupled neural maps, is functional.

Basically, agents are going to play the imitation game (de Boer 2000). They possess the two neural maps presented earlier, which work in the same manner. Additionally, each of them have repertoires of syllables (here sequences of $N=3$ targets), and one game consists in having one agent, the speaker, choose one of its items, then utter it, and then have another random agent, the hearer, try to imitate it by producing the closest syllable in its repertoire. After the imitation, the speaker categorizes the utterance he heard and checks if it corresponds to the category of the syllable he pronounced initially. He then gives a binary (good or bad) feedback to the hearer. The items of their memories have scores (num. of times used successfully / num. of times

Figure 2: Neural maps and attractors after 1000 interactions, corresponding to the initial states of figure 1)

Figure 3:

used). This is used to prune the syllables which are not efficient. Initially, repertoires are empty. They grow either by imitation (agents hear a syllable that they can not imitate and yet have used a usually efficient syllable prototype), or by invention. Inventing a syllable consist in choosing randomly $N=3$ targets by activating three random neurons of the articulatory map. As the receptive field of these neurons are initially uniformly spread across the space, inventions at the beginning of simulations will produce syllables whose targets are uniformly spread across the space. This means exactly non phonemically coded.

This model can be tuned to show that only our non-functional hypothesis is plausible in a realistic explanatory setting : this can be done by using a realistic synthesizer or not, coupled with the ability to deactivate the learning rule of neural maps (neurons do not update their receptive fields when they perceive a stimulus). If the use of a realistic synthesizer with a deactivated learning rule does not provide phonemic coding, this does show that the

Figure 4:

morpho-innatist hypothesis is not sufficient, and as (Oudeyer 2002) showed it was not necessary either, the conclusion is that this is not a good candidate (in fact, here we would show even more : the combination of morpho-perceptual constraints and functionalism is not sufficient). If we use an abstract synthesizer with a deactivated learning rule, then if we do not get phonemic coding, Lindlom's functionalism is not sufficient either (and again, we showed it was not necessary). Then, if each time we activate the learning rule we do get phonemic coding, this will confirm the plausibility of the exaptationist hypothesis of (Oudeyer 2002).

A measure of phonemic coding of a syllable systems was developed in (Oudeyer 2002). This consists in making models of the distributions of targets, based on parzen windows : at points corresponding to a the crossings of a regular grid, one approximates the local probability density function by averaging the values of a gaussian function (centered on this point) taken at all points coded by each targets. This is very similar to making multi-dimensional histograms, and counting how many targets fall in each bin. Yet, using gaussians gives a fuzzy binning whose choice of variance is much easier than the choice of bin size in the case of histograms. This approximation is used to compute the entropy of target distributions : if they are uniformly spread, entropy is maximal, and the more they are clustered, the lower the entropy. Thus, this is a way to automatically monitor the clusteredness of targets, and so how much a system is phonemically coded.

A first series of experiment ¹ was conducted with the abstract articulatory synthesizer. A first parameter that could be varied (apart from the use or not of the learning rule), was the dimensional-

¹let us mention that the mechanism described here does allow the cultural building of a syllable systems with which agents can imitate each other successfully. Results identical to what was described in (Oudeyer 2001) were found here. This is a significant progress compared to other other models of the origins of sound systems, but we will not give details here since it is not the main topic this paper

ity of the motor and perceptual spaces. Indeed, this is interesting since the goal of agents is to position syllable prototypes in these spaces such that they are not confused. Hence, the fact that increasing linearly the number of dimensions does increase exponentially the volume of the spaces might have some consequences. Figure 3 presents the average entropies of syllable systems composed of 40 syllables, and generated by populations of agents using or not the learning rule. For each case, 50 experiments were ran and the mean entropy and standard deviation were measures. We added a "uniform" column corresponding to the entropy of syllable systems target distributions generated randomly (uniformly distributed). The values of "uniform" thus characterize syllable systems which are absolutely not phonemically coded. We do observe that except for dimension 1 (which is not very realistic), the use of the learning rule does generate phonemically coded systems while when it is not used, systems have entropies equal to the uniform case : they are not phonemically coded. A second set of experiments consisted in keeping the dimensionality of motor and perceptual spaces equal to 2 and see whether the amount of noise would change anything (noise proved to be of importance in the experiments of de Boer 2000). Figure 4 shows that even a large amount of noise (30 percent) does not push the system to be phonemically coded when it does not use the learning rule, while using it still gives phonemically coded systems when noise gets high (yet it becomes less and less phonemically coded, which is normal since when the noise is too high, this is equivalent to reshuffling permanently and completely all targets).

A second series of similar experiments were made using the realistic articulatory synthesizer. Figure 5 shows the results, when noise is again varied : we see that even if a realistic synthesizer is used, no phonemic coding is obtained if the learning rule is not used. And again, as soon as it is used, and if the noise remains reasonable, we do get phonemic coding.

As a consequence, neither morpho-perceptual innatism nor functionalism is sufficient to explain phonemic coding.

Conclusion

(Oudeyer 2002) presented a new hypothesis for the origins of phonemic coding, which had the a priori advantage of being more simple and requiring less assumptions than other models. In this paper we presented a general model of the origins of syllable systems, which in addition to solve the 2-level problems faced by previous research in the origins of sound systems, allows to test all hypothesis on a common ground. We showed that clearly the morpho-perceptual innatism and Lindblom's functionalism are neither necessary nor sufficient to ex-

Figure 5:

plain phonemic coding. We did not prove that the non-functional side effects of our coupled neural maps model are necessary (but a better hypothesis has to be invented and validated to prove they are not), but they are sufficient, and so the only existing satisfying candidate to explain phonemic coding.

Abstract

In terms of their semantic and pragmatic properties, number expressions (*one, two, three...*) have standardly been considered similar to quantifiers (*some, a few, all*). For instance, both kinds of expression form a scale: typically, an assertion containing a weaker member of the scale (*Some/Two of the dwarfs loved Snow White*) can be used to implicate that the stronger term of the scale doesn't apply (*Not all/No more than two of the dwarfs loved Snow White*). We report here results from two experiments with young speakers of Modern Greek which support the opposite conclusion: namely, that number terms and quantifiers behave differently in terms of the scalar inferences they support. We discuss implications of these findings for linguistic theories of the semantics/pragmatics of numerals, as well as for developmental theories of the acquisition of number words.

Introduction

In terms of their semantic and pragmatic properties, number expressions (*one, two, three...*) have standardly been considered as scalar expressions similar to quantifiers (*some, a few, all*). Semantically, both numerals and quantifiers have been assigned an 'at least' meaning (Horn, 1972; Grice, 1989): on this 'minimalist' analysis, *two* means *at least two* and *some* means *some (and possibly all)*. Pragmatically, both numerals and quantifiers can be used to give rise to so-called *scalar implicatures*. Such implicatures arise when a speaker uses a weak member of the numerical or quantificational scale in order to implicate that the stronger term of the scale does not hold. For instance, an utterance such as (1) is typically used to implicate (2):

- (1) *Some/Two of the dwarfs loved Snow White.*
- (2) *Not all/No more than two of the dwarfs loved Snow White.*

The derivation of scalar implicatures is generally assumed to follow Gricean lines: for instance, if the speaker knew that the more informative statement with *all* (or a higher numeral) were true and relevant, other

things being equal, s/he would have preferred to use it. The fact that s/he didn't offers grounds for assuming that such a more informative statement isn't true.

More recently, several objections have been raised to the view that the scalar semantic/pragmatic profile of numerals is identical to that of quantifiers (Carston, 1985; 1998; Horn, 1992). First, it has been observed that cardinals, but not 'inexact' quantifiers, can feature in contextually induced reversals of scale: in (3), *three* is used to communicate *at most three*:

- (3) These houses are big enough for families with three kids.

But it is not possible to use *some* in a similar way (e.g. to implicate *at most some*). Second, number terms are regularly used with an 'exact' interpretation in mathematical statements (*Two plus three makes five*), a fact which is hard to reconcile with an 'at least' semantics for numerals (unless we assume that cardinals are ambiguous). Third, the scalar properties of numerals disappear under incorporation: a four-sided figure has exactly (not at least) four sides. Finally, approximation seems to work differently with numerals: *I have \$300* is more likely to receive an 'at least' interpretation than its unrounded counterpart *I have \$300.17*. For these and related reasons, it has been proposed that cardinals are, in fact, distinct from other scalar expressions. According to these proposals, numerals do not have an 'at least' semantics upper-bounded by a scalar implicature; rather, they are best analyzed as underspecified among an 'at least', 'exact' and 'at most' reading. Pragmatic considerations then are used to determine which reading is more appropriate in a specific context.

There is by now a vast linguistic literature which attempts to adjudicate between the 'minimalist' proposal and alternative theories for number terms (for reviews, see Carston, 1998; Levinson, 2000). The outcome of this debate is important, since theories of scalar predication are a valuable source of insights about how semantic information and contextual cues co-ordinate with each other and contribute to utterance meaning.

In this paper, we present the results from two developmental studies which compare the semantic-pragmatic properties of both cardinals and quantifiers. Our goal is to use the scalar behavior of numerically modified and quantified phrases in child language to shed light on the theoretical debate surrounding these predicates. To preview our discussion, we find that number terms and quantifiers behave differently in child language in terms of the scalar inferences they support. We take these results to be incompatible with 'minimalist' semantic accounts of numerals. Thus we show that developmental data offer an additional piece of evidence for the different status of numerals and quantifiers within semantic/pragmatic theories.

Our experiments build on previous cross-linguistic studies of the acquisition of scalar predicates (for English, see Chierchia, Crain, Guasti, Gualmini & Meroni, 2001; Gualmini, Crain, Meroni, Chierchia & Guasti, 2001; Musolino & Lidz, in press; for French, see Noveck, 2001). Even though they were not concerned with the pragmatics of number terms, these studies have shown that preschoolers have difficulty with the pragmatics of other scalar expressions such as quantifiers (even though they seem to know the semantics of such quantifiers). In our experiments, we turn to Modern Greek for further evidence. Since the scalar inferences associated with numbers and quantifiers apply universally, we should expect to see cross-linguistic similarities in the acquisition of the pragmatics of scalar predicates.

Experiment 1

Methods

Participants. Participants were a group of 20 Greek-speaking 5-year-olds between the ages of 4;11 and 5;11 (mean 5;3) and a group of 20 adult native speakers of Greek. The children who participated in this study were recruited from daycares in the Athens area. The adults were all undergraduate students at the University of Athens.

Procedure and Materials. In this experiment, we asked children (and adults) to offer pragmatic judgements on sentences containing either the numerical scale <three, two> or the quantifier scale <all, some>.¹ We used a slightly modified version of the Truth Value Judgment Task (Crain & Thornton, 1998). The TVJT typically involves two experimenters. The first experimenter acts out short stories in front of the subjects using small toys and props. The second experimenter plays the role of a puppet (in this case

Minnie) who watches the stories alongside the subjects. At the end of the story, the puppet is asked to say what happened in the story. In our version, instead of asking subjects if the puppet is 'right' or 'wrong' (as in the original TVJT), we then asked whether the puppet 'answered well' (i.e., *Apantise kala*; 'Did-(she)-answer well?'). This modification was made since we were interested in felicity, not truth. Finally, the subjects were asked to justify their answers by explaining why they thought that Minnie answered well or not.

The children were tested individually in a quiet room away from the class. Adult subjects were shown a videotaped version of the stories witnessed by the children, including the warm-up stories. They were given a score sheet and were instructed to indicate, for each story, whether Minnie had 'answered well' or not. They were also asked to provide a brief justification for their answers.

For each scale, subjects were asked to judge four statements like the ones in (4-5):

- (4) Meriki apo tus dinosavrus efagan dedra.
'some of the dinosaurs ate trees'
- (5) Dio apo tus dinosavrus efagan dedra.
'two of the dinosaurs ate trees'

In each case, these utterances were used to describe situations which satisfied the truth conditions of utterances containing stronger terms on the respective scales, i.e., *all*, *three*. The critical stories were identical for both scales. For instance, for both (4) and (5), a group of three dinosaurs went to get something to eat. After contemplating other options, all three dinosaurs ended up eating trees. In this context, assuming an 'at least' semantics for the scalar predicates, both utterances in (4) and (5) express a true but pragmatically infelicitous proposition.

Before the main phase of the experiment, each child received two 'warm-up' stories, one designed to elicit a 'Yes' answer and the other a 'No' answer. Furthermore, in addition to the critical statements, and for each scale, subjects were asked to judge four control statements like the ones in (6-7):

- (6) Donald cleaned some of the cars/airplanes.
- (7) Donald cleaned two of the cars/airplanes.

The purpose of these controls was to ensure that subjects, and in particular children, could accept or reject the puppet's statements when appropriate and, more importantly, that they could do so when these statements involved felicitous uses of terms like *some* and *two*. For each control statement, the experimenter had a choice between two versions: one that was a correct description of the story and would therefore elicit a 'Yes' response and one that was an incorrect

¹ For ease of exposition, we provide English glosses throughout. The Greek terms are <tris, dio> and <oli, meriki> respectively.

description of the story and would therefore elicit a 'No' response. The experimenter selected the version of the control statement (correct or incorrect description) based on the child's response of the preceding critical statement. If the child had rejected the puppet's statement on the previous critical trial, the experimenter selected the version of the control statement that would elicit a 'Yes' response, and vice-versa. This step was taken to keep a balance between 'Yes' and 'No' responses.

Subjects (5-year-olds and adults) were randomly assigned to one of two conditions, determined by scale type (i.e., *<all, some>*, *<three, two>*) which gave rise to a 2X2 design with age and scale type as between subject factors and 10 subjects per cell. The age range and mean ages for the 10 children assigned to each scale condition, i.e. *<all, some>* and *<three, two>*, are 5;0 to 5;11 (mean 5;4) and 4;11 to 5;10 (mean, 5;3) respectively. In each condition, subjects received four critical trials and four control trials administered in a pseudo-random order. Within each condition, order of presentation was counterbalanced between subjects.

Results

Beginning with test trials, we found that adult subjects overwhelmingly rejected the puppet's statements in each of the two conditions, i.e. 92.5% of the time in the *<all, some>* and 100% of the time in the *<three, two>* condition. Statistical analysis revealed no reliable difference between these rejection rates ($t(18) = 1.96$, $p = 0.06$). By contrast, we found that while 5-year-olds rejected the puppet's statements in the case of *<three, two>* 65% of the time, they did so reliably less often in the case of *<all, some>* i.e., 12.5% of the time ($t(18) = 3.47$, $p < 0.01$). The proportions of 'No' responses were entered into an analysis of variance (ANOVA) with two factors: age (5-year-olds vs. adults) and scale type (*<all, some>* vs. *<three, two>*). The analysis revealed a main effect of age ($F(1,36) = 54.41$, $p < 0.0001$), a main effect of scale type ($F(1,36) = 14.81$, $p < 0.001$) and a reliable interaction between age and scale type ($F(1,36) = 8.33$, $p < 0.01$).

Recall that subjects in this study were also asked to provide justifications for their answers. Adults in 98% of the justifications they offered for rejecting a statement made reference to the stronger term of the scale, as expected. That is, they said that the puppet was wrong that some or two of the dinosaurs ate a tree because ALL or THREE of them had eaten a tree. Children's justifications for rejecting a numerically modified statement always invoked the pragmatically more appropriate stronger numeral. The same is true for the few cases in which a quantified statement with *some* was rejected by children.

On control trials, adults gave correct responses 100% of the time in the *<all, some>* condition and 80% of the time in the *<three, two>* condition. No reliable difference was found among these means ($t(18) = 1.92$, $p = 0.07$). On the same items, children gave correct responses 90% of the time for *<all, some>* and 95% of the time for *<three, two>*. Again, no reliable differences among the means were found ($t(18) = .77$, $p = 0.44$).

Discussion

Two main conclusions emerge from the first experiment. First, children are much less likely to compute scalar implicatures than adults. This finding comports well with previous research showing that preschoolers cross-linguistically have difficulties understanding scalar inferences, especially those associated with quantifiers (Chierchia et al., 2001; Gualmini et al. 2001; Musolino & Lidz, in press; Noveck, 2001). Second, and more crucially for present purposes, 5-year-old children are more successful in drawing scalar inferences triggered by numerals than by quantifiers. This finding is even more remarkable given that our critical trials with *some* and *two* used identical scenarios and props. This result is unexpected given standard 'minimalist' semantic accounts, since it points to a difference in status between numerals and inexact quantifiers such as *some*.

On the basis of the available evidence on children's performance with scalar inferences, previous literature has concluded that children are generally incapable of deriving scalar implicatures on-line (Chierchia et al., 2001). It might be tempting to interpret our results (at least for *some*) in a similar way. However, there are alternative hypotheses which are worth pursuing. For instance, it is possible that children's failures are not due to an inability to derive the implicatures but to a misunderstanding of the nature of the task. Perhaps children (unlike sophisticated adult communicators) treat this as a truth-value judgement task. Since no special motivation is provided for drawing the scalar inferences, children may be more willing to let the puppet score an appropriate response if she has simply given a true (albeit infelicitous) description of what happened. This inability to correctly assess the experimental demands may therefore make preschoolers in our study appear less pragmatically savvy than they really are (for similar explanations of children's 'failures', see Shipley, 1979; Gelman & Greeno, 1989). Our aim in designing Experiment 2 was to investigate whether a methodologically improved version of the same task might raise children's overall performance with scalar terms. We were also interested in testing whether such a task would yield a similar asymmetry between cardinals and quantifiers.

Experiment 2

Methods

Participants. 20 Greek-speaking children ranging in age between 5;1 and 6;3 (mean 5;6) participated in this experiment. These children were recruited at daycare centers in the same Athens area as the children used in Experiment 1.

Materials and Procedure. Experiment 2 introduces several modifications to the design of our previous study. First, we included a training phase, in which we presented children with four warm-up stories designed to enhance their awareness of the fact that they were being asked to produce pragmatic judgments. Children were told that the puppet, Minnie, sometimes said 'silly things' and that the purpose of the game was to help Minnie 'say things better'. For example, Minnie would be shown a toy dog which she would describe using the truth-conditionally accurate - but pragmatically infelicitous - statement 'This is a little animal with four legs'. The child would then be asked whether 'Minnie answered well' and whether 'we can say it better'. In case the child failed to correct the puppet and provide a better description, the experimenter eventually corrected Minnie and provided the appropriate description, i.e. 'Minnie didn't say that very well. This is a DOG'.

The second change we introduced concerns the test scenarios. As before, subjects witnessed four test stories in which they were asked to judge statements containing the scalar terms *some* and *two* in situations which satisfied the truth conditions of the stronger terms of the respective scales, i.e. *all* and *three*. However, the stories in Experiment 2 were all based on scenarios in which the main character was involved in a contest or a challenge. The main character's performance therefore became the focal point of the stories and at the end, the puppet was asked to comment on how well the character in question had done, 'How did X do?' (*Pos ta pige o X?*). In one of the stories for example, one of the characters claims that he is very good at throwing hoops around a pole and he challenges Mickey to try and do the same with three hoops. Mickey really concentrates hard and he's able to put all the hoops around the pole. At the end of the story, Minnie is asked "How did Mickey do?" and she answers by saying that "Mickey put some of the hoops around the pole". The idea behind this manipulation is to make clear the demands of the communicative situation: given that Mickey's performance is being directly evaluated, only an answer making reference to *all* the hoops would satisfy the expectations of the hearer.

Children heard four test stories and four control stories administered in a pseudo-random order. As before, order of presentation was counterbalanced between subjects within a single condition. Finally, as in Experiment 1, subjects were randomly assigned to either of the two scale conditions. The age range for the 10 children assigned to the quantifier scale condition was 5;1 to 6;2 (mean 5;6). For the number scale condition, the range was 5;4 to 6;3 (mean 5;7).

Results

As before our dependent measure was children's *Yes/No* responses to the puppet's statements. We found that the manipulations described above led children to reject the puppet's statements much more often than in Experiment 1. Nevertheless, the difference between scales persisted: children answered correctly 52.5% of the time for the *<all, some>* scale, and 90% of the time for the *<three, two>* scale ($t(18) = 2.39$, $p = 0.02$). We compared the rejection rates from Experiment 1 and Experiment 2 by entering them into a 2 (training vs. no training) by 2 (scale type) ANOVA. The analysis revealed a main effect of training ($F(1,36) = 8.92$, $p < 0.01$), a main effect of scale type ($F(1,36) = 17.1$, $p < 0.001$) and no reliable interaction between training and scale type ($F(1,36) = 0.47$, $p = 0.49$). On control items, children gave correct responses 85% of the time in the quantifier condition and 95% of the time in the number condition. No reliable differences between these means were found ($t(18) = 0.89$, $p = 0.38$). Finally, the justifications children offered for their rejections in the overwhelming majority of cases (93%) made explicit reference to the stronger term of the scale (just like adults' justifications in Experiment 1).

Discussion

The results from this Experiment show that children's sensitivity to scalar inferences improves dramatically if children are provided with clear contextual cues about the communicative expectations of the task.² This is an important and novel finding in itself (see Papafragou & Musolino, 2001, for discussion). For present purposes, a more pertinent finding is that the asymmetry found in the previous experiment persists: in child language,

² Children in Experiment 2 are slightly older than those in Experiment 1. However, there are strong reasons to think that the differences in performance are not due to these small age differences. First, in the *<all, some>* case, the age difference is not reliable (mean 5;4 vs. 5;6, $t(18) = 0.985$, $p = .33$) but the difference in performance persists. Second, and more importantly, previous studies have reported children's difficulties with scalar implicatures well beyond the age of 5;0 (and up to the age of 10;0).

numerically modified phrases give rise to scalar inferences much more readily than quantified phrases.

General Discussion

As we mentioned in the introduction, there are several theoretical reasons for considering cardinals as distinct from quantifiers and other scalar terms, and our experimental data seem to confirm this difference. Our studies demonstrate that, in child language, inexact quantifiers such as *some* are assigned a lower-bounded reading ('at least some', or 'some and possibly all') and the associated scalar inferences are ignored in the absence of strong contextual cues. By contrast, preschoolers typically reject lower-bounded interpretations of numerals and are very attentive to the scalar properties of number terms. Since the test environment was identical in both situations, this difference in interpretive preferences points to a difference in the semantic/pragmatic status of numbers and quantifiers. Specifically, it suggests that, while a minimalist semantics may be plausible for quantifiers and other scalar predicates, cardinals may best be analyzed in terms of either an 'exact' or an underspecified semantics.

An interesting observation which arises from our experiments is that children often used the counting routine as a means of formulating their responses. For instance, when Minnie offered *Two of the dinosaurs ate trees*, several children protested by saying *No, one, two, THREE dinosaurs ate trees* (while at the same time pointing to and counting the dinosaurs one by one). Explicit counting of this sort offers a specific and precise way of verifying statements containing number terms (by placing the referents of the corresponding NPs in a one to one correspondence with objects in the world). Counting games may also encourage an 'exact' interpretation of the numerals. Notice that neither of these steps is available for the inexact *some*.

There is additional evidence that the observed asymmetry between quantifiers such as *some* and numerals is related to the difference between discrete and non-discrete (vague) scalar predicates. Papafragou (2002) tested Greek preschoolers' understanding of the scalar modifier *half* (e.g. *The bear built half of the tower*). This modifier resembles numerals in that it is discrete (it denotes a precise partitioning of a quantity into two equal parts). By means of the same methodology as the second experiment reported above, it was found that young Greek learners rejected lower-bounded interpretations of the modifier *half* in contexts which licensed scalar implicatures. For instance, children overwhelmingly rejected the statement *The bear built half of the tower* in cases where a whole tower had been built. This pattern reinforces the conclusion that discrete quantity modifiers (e.g. *half*,

numerals) have distinct properties from inexact quantifiers and other scalars (e.g. *some*, *a few*).

Although our results can be taken as evidence against a minimalist semantics for numerals, they leave open the question of whether number terms in natural language have an exact or an underspecified semantics. It is worth pointing out that, in the considerable developmental literature which looks at children's acquisition of number terms (Carey, 2001; Gelman & Gallistel, 1978; Wynn, 1992; Bloom & Wynn, 1997, among many others), it is usually assumed that children ultimately arrive at an 'exact' semantics for number terms (which is the correct adult meaning). Moreover, according to one influential position, children assign meaning to cardinal expressions in natural language by placing them in a one-to-one correspondence with an innate conceptual 'integer list' (Gelman & Gallistel, 1978). The results reported in this paper, even though not univocally in favor of an 'exact' over an underspecified semantics for numerals, are certainly consistent with these positions.

To conclude: Throughout this paper, we have assumed that aspects of child language can be instructive about the nature of the semantic representations in adults. This position accepts some fundamental continuity in the representational systems of children and adults - here, in the specific domain of number. It thus allows us to bring acquisition data to bear on theoretical debates about the architecture of the semantic-pragmatic system in adults. Even though several interesting questions remain unresolved about both the adult system and its acquisition by young learners, we hope to have shown that an approach which treats numbers as regular scalar predicates alongside quantifiers misses important generalizations about their developmental properties.

Acknowledgments

We wish to thank Lila Gleitman, Henry Gleitman, John Trueswell, and the members of the CHEESE seminar at the University of Pennsylvania for comments and input. Thanks go to the teachers and children at the 3rd and 5th daycares at Vrilissia (Athens), and to Profs. D. Chila-Markopoulou, D. Theofanopoulou-Kontou and S. Hoidas for the experiments conducted at the University of Athens. This research was supported by NSF-STC Grant #SBR-89-20230, and by NIH Grant #1-R01-HD37507-01L.

Abstract

Complex Problem Solving (CPS) is a hybrid between field studies and experimental studies. This paper introduces a new, abstract conceptualization of *microworlds* research based on two innovations: (1) a problem representation, which treats protocols as objects in a feature space and, (2) a similarity metric which is defined in this problem space. Latent Semantic Analysis (LSA) is used to analyze performance in CPS, using actions or states as units instead of words and trials instead of text passages. Basic examples of applications are provided, and advantages and limitations are discussed.

Introduction

Many real-world decision making and problem solving situations are (1) *dynamic*, because early actions determine the environment in which subsequent decision must be made, and features of the task environment may change independently of the solver's actions; (2) *time-dependent*, because decisions must be made at the correct moment in relation to environmental demands; and (3) *complex*, in the sense that most variables are not related to each other in one-to-one manner. In these situations, the problem requires not a single decision, but a long series of decisions which are dependent on one another. For a task that is changing continuously, the same action can be successful at moment t_1 and useless at moment t_2 . However, traditional, experimental problem solving research has focused largely on tasks such as anagrams, concept identification, puzzles, etc. that are not representative of the features described above.

In Europe, researchers led by Broadbent (e.g., Broadbent, 1977) in the UK and Dörner (e.g., Dörner, 1975) in Germany, were concerned about that fact and started working on a set of computer-based, experimental tasks that are dynamic, time-dependent, and complex, called *Microworlds*¹. The study of microworlds is an example of Complex Problem Solving (e.g., French & Funke, 1995).

¹ This term sometimes has other meanings. For example, educational applications created to teach physics (Henderson, Klemes, & Eshet, 2000), simulated words in the early AI programs like the block word of SHRDLU, (Winograd, 1972) and static tasks to study decision making (Green, 2001) have been called

Compared to traditional Problem Solving, Complex Problem Solving (CPS) radically changed the kind of phenomena reported, the kind of explanations looked for, and even the kind of data that were generated. However, the results obtained to date are far from being integrated and consolidated. This fact led Funke to affirm that 'Despite 10 years of research in the area, there is neither a clearly formulated specific theory nor is there an agreement on how to proceed with respect to the research philosophy. Even worse, no stable phenomena have been observed' (Funke, 1992, p. 25). Almost another 10 years after Funke's argument, although more empirical research has been conducted in the area, we cannot say that the situation has changed drastically. At this moment, there is no theory able to explain even part of the specific effects that have been described or how they can be generalized.

A theory of generalization and similarity is as necessary to psychology as Newton's laws are to physics (Shepard, 1987). However, for CPS there is no common, explicit theory to explain why a complex, dynamic situation is similar to any other situation or how two slices of performance taken from a problem solving task can possibly be compared quantitatively (Klein, Orasanu, Calderwood, & Zsombok, 1993). This lack of formalized, analytical models is slowing down the development of theory in the field. At least two problems make it difficult to apply the classical problem solving approach to CPS, one theoretical and one methodological:

(1) The utility of state space representation for tasks with inner dynamics is reduced because in most CPS environments it is not possible to undo the actions. For example, imagine that two participants in *Firechief* (see below) are in an identical situation (system state) when the trial starts. One of them proceeds to make a control fire on the east side of a fire, while the other one is preparing a control fire on the north front of the fire. After these actions, the system state is no longer identical for them. Now they have to cope with rather different problems. Moreover, if the first participant wants to apply the same technique that

Microworlds. However, we are concerned here only with tasks that fulfill the conditions described above.

the second participant used, there is absolutely no way to come back to the initial state and begin with a new strategy. This situation is not an issue in static tasks like the tower of Hanoi problem because it is always possible to undo a wrong action. Feedback delays (e.g., Brehmer, 1995; Gibson, 2000) and an upsettingly large number of possible states (e.g., Dörner, 1975; Omodei and Wearing, 1995) contribute to the reduced utility of the state space approach.

(2) Traditional methods of knowledge elicitation are not always applicable: Concurrent verbal protocols consistently interfere with performance (Dickson, Omodei & Wearing 2000); measures based on relatedness judgments like rating correlations or pathfinder distance correlations are not sensitive to context manipulations in naturalistic task like fire fighting (Calderwood, 1989).

In this paper we introduce a theory and methodology for CPS tasks based on Latent Semantic Analysis (LSA, Landauer and Dumais, 1997). The theory addresses issues concerning the induction, representation, and application of knowledge. Basically, LSA infers knowledge from the many weak constraints that are present in complex problem solving situations.

LSA does not represent all the possibilities of a system (the system's state space), but only the paths that people have actually followed when interacting with it. This offers a realistic view of how the system is understood and used by humans. LSA is a *computational* theory on how environmental constraints are learned and how they can be described. In terms of Simon's classical parable of 'the ant and the beach' (Simon, 1981, p. 63), one could say that LSA describes and infers the shape of the beach from the thousands of tracks the ants have left on the beach. In this sense, LSA can be conceived as a computational extension to theories for describing environmental constraints, such as the abstraction hierarchy (Rasmussen, 1985; Vicente, 1999).

LSA has several interesting features that make it a suitable technique for analyzing performance on a complex, dynamic task:

(1) It does not assume independence of decisions; indeed, it uses dependencies between decisions to infer structure. Some methods employed in the past treated CPS performance in a way that assumed that decisions are independent or have short-term dependencies only.

(2) LSA reduces the dimensionality of the space. Imagine a hypothetical problem solving task that, when performed from the beginning to the end, traverses 300 states. Furthermore, let us assume that every state is described by 6 dichotomous variables ($2^6 = 64$ possible states). Since we have 300 states in our sample of performance, there are $64 \times 300 = 19200$ possible paths in this task. Every sample would be represented as a matrix of $6 \times 300 = 1800$ values. With LSA, every sample is represented as a vector of only 100-300 values.

(3) There are no *a-priori* assumptions about 'the beach'. In most of the analysis performed on *microworld* data the

experimenter has to impose some structure (*a-priori*, theoretically driven assumptions) on the data. However, the selection of this theoretical structure (How many strategies are possible? How many strategies are representative? Are they generalizable to different conditions?) can bias the analysis. The LSA approach is self-organizing, and does not require defining an *a priori* theoretical structure, as will be shown below.

Before we start describing what LSA is and how it can be applied to CPS, we would like to stress some abstract considerations that underlie the approach that we are about to implement. These considerations are independent of the procedure itself (other procedures could be defined using this framework), but, in our opinion, an essential step to dealing with the complexity of the tasks at hand: (1) each microworld can be conceptualized as a complex, multidimensional feature space. (2) To address the intractability problem, we usually need to create a representation or transformation of this original multidimensional feature space. To do this, we need to find a set of features that represent the characteristics that make participants different, and to delete those that are not important. (3) Last, each trial of every subject can be conceptualized as an implementation of several values in the feature space. Not only a trial, but every subpart or superpart of a participant's performance (strategies or performance patterns) can be thought of as an object in this space.

We shall illustrate how LSA can be used to analyze CPS tasks, using the *Firechief* microworld as an example.

Description of the example application task

Firechief (Omodei & Wearing, 1995) simulates a forest where a fire is spreading. Participants' task is to extinguish the fire as soon as possible. In order to do so, they can use helicopters and trucks (each one with particular characteristics) that can be controlled by mouse movements and key presses. There are three commands that are used to control the movement and functions of the appliances: (1) Drop water on the current landscape segment; (2) Start a control fire (trucks only) on the current landscape segment; (3) Move an appliance to a specified landscape segment.

Every time a participant performs an action, it is saved in a log file as a row containing action number, command (e.g. drop water or move) or event² (e.g., a wind change or a new fire), current performance score, appliance number, appliance type, position, and landscape type. Most of these variables are not continuous, but on a nominal scale, such as type of movement. For more information on the structure of the log files, see Omodei and Wearing (1995).

² Events are generated by the system, while actions are generated by the user. Events are also lines in the log file. Only 1-2% of the lines in a log file are events.

The set of trials that was used in this report (referred as *corpus*) was obtained in four experiments described in Quesada, Cañas, & Antoli (2000) and Cañas, Quesada, Antoli & Fajardo (submitted).

Description of LSA

LSA is a machine-learning model that induces representations of the meaning of words by analyzing the relation between words and passages in large bodies of text. LSA is both a method (tool) used to develop technology to improve educational applications, and a theory of knowledge representation used to model well known experimental effects in text comprehension and priming, among others (Landauer & Dumais, 1997). Latent Semantic Analysis was originally developed in the context of information retrieval (Deerwester, Dumais, Furnas, Landauer, & Harshman, 1991) as a way of overcoming problems with polysemy and synonymy. Some words appear in the same contexts (synonyms) and an important part of word usage patterns is blurred by accidental and inessential information. The method used by LSA to capture the essential semantic information is dimension reduction, selecting the most important dimensions from a co-occurrence matrix decomposed using Singular Value Decomposition (see below). As a result, LSA offers a way of assessing semantic similarity between any two samples of text in an automatic, unsupervised way.

LSA has been used in applied settings with a high degree of success in areas like automatic essay grading (Foltz, Laham, & Landauer, 1999) and automatic tutoring to improve summarization skills in children (E. Kintsch, Steinhart, Stahl, Matthews, Lamb, & the LSA Research Group, 2000). As a model, LSA's most impressive achievements have been in human language acquisition simulations (Landauer & Dumais, 1997) and in modeling of high-level comprehension phenomena like metaphor understanding, causal inferences and judgments of similarity (Kintsch, 2001).

Although LSA has been mostly used on text corpora, our basic point is that LSA can be applied to any domain of knowledge where there are a high number of weak relations between tokens, as in CPS log files. Instead of word usage statistics obtained from huge samples of text, we have used a representative amount of activity in controlling dynamic systems, and actions or states have been used to develop an objective measure of similarity in the changing, time-dependent, highly complex experimental tasks known as *microworlds*. The next sections show the basic steps involved in this analysis and presents some examples of the powerful results that can be obtained thereby.

LSA applied to Microworlds

LSA starts with the creation of a matrix of actions by trials. Note that this is not an exhaustive state space, or a mapping

of all possible transitions between actions, since in most of the systems – other than small ones like Hayes & Broadbent's (1988) sugar factory and the like - this task would be excessively demanding (see Buchner, Funke & Berry, 1995). Our corpus was composed of 360,199 actions in 3441 trials. Among them, only 75,565 were different actions, which means that on average each action appears 6.25 times in the corpus. Note that we are representing *only* the information that actual people interacting with the system experienced, not all possible actions in this microworld.

Each of these 75,565 rows stands for a unique action, and each of the 3441 columns stand for a trial. Each cell contains the frequency with which the action of its row appears in the trial denoted by its column. Note that most of the cells will contain a frequency of zero, since most actions appear in only a few trials and not in the rest.

This matrix of frequencies is decomposed using Singular Value Decomposition (SVD). Any matrix can be decomposed and then recomposed perfectly using only as many factors as the smallest dimension of the original matrix. However, an interesting phenomenon occurs when the original matrix is recomposed using fewer dimensions than necessary: the reconstructed matrix is a least-squares best fit. When the actions-by-trials matrix is recomposed using a small fraction of the available dimensions (usually between 100 and 300 dimensions), the new matrix contains information that has been inferred from the dependencies between actions and the context where these actions appeared. In fact, the contexts where these actions did not appear are as important - carry as much information - as those where they did. The microworld is a new multidimensional feature space, where both actions and context (trials) are represented in a way that amplifies those characteristics that make participants different, and delete those that are not important for classifying their performance.

Some examples of possible analysis

LSA allows us to measure the functional similarity between actions in CPS tasks. Some actions can be considered as *functional synonyms*: they appear in the same contexts, and fulfill approximately the same function. The following example illustrates this idea.

Table 1: Example of how LSA captures similarity at a molecular (action) level

	Time <i>t1</i>	Time <i>t2</i>
Example 1	move_11_9_forest	Drop_11_9_forest
Example 2	move_15_15_forest	Drop_15_15_forest
Example 3	move_10_9_forest	Drop_10_9_forest
Example 4	move_11_9_forest	control_11_9_forest

In Table 1, four different actions some actions are shown. For simplicity, some variables that are normally contained in the log files have been removed. Example1 contains a movement to the point (11, 9) in the screen, which is of type *forest*, and then, a drop water action there. Example 3 shows a very similar picture, where the movement is done to a contiguous cell (10,9) that is also of type *forest*. From a human point of view, these two examples are highly similar. For LSA they are too, as can be seen in their similarity expressed as a cosine of 0.854 in Table 2.

Table 2: Similarities between Table 1 examples (cosines).

	Example 1	Example 2	Example 3	Example 4
Example 1		0.124	0.854	0.662
Example 2			0.1259	0.077
Example 3				0.566
Example 4				

The second example has a rather different meaning since the cell targeted is (15,15), quite far from the cell used in examples 1 and 3. The cosines between them and example2 (.124 and .125) are, accordingly, smaller than the one between 1 and 3.

Example 4 describes an action that has been performed in the same cell as in example 1 (11,9), but this time is a control fire instead of a drop-water action. The cosine between 1 and 4 is high (0.56), expressing a certain similarity between the two actions, but not as high as in examples 1 and 3, where the objective similarity is more evident.

Tables 3 and 4 present a more complex example where wider slices of performance (8 actions) are compared. The samples labeled Example1, Example2, and Example 3 are beginnings of trials that have been selected randomly from the *corpus*. This time, all the usable information contained in the log file is displayed. Each action has six components: type of action, appliance number, appliance type, departure cell, arrival cell and type of arrival cell.

Table 3: First 8 movements in 3 slices randomly sampled from the *Firechief* experiments described in Quesada et al. (2000) and Cañas et al. (submitted). When an action is shared by two extracts, it is marked as a shaded cell.

Example 1	Example 2	Example 3
move_2_truck_4_11_13_3_forest	move_2_truck_4_11_12_15_forest	move_2_truck_4_11_2_2_pasture
move_1_truck_4_14_16_14_forest	move_1_truck_4_14_13_5_forest	move_1_truck_4_14_0_5_forest
move_3_copter_8_6_11_12_forest	move_4_copter_11_4_11_9_forest	move_4_copter_8_6_8_4_clearing
move_4_copter_11_4_11_9_forest	drop_water_4_copter_11_9_forest	move_3_copter_8_6_8_10_clearing
Control_fire_2_truck_13_3_forest	move_4_copter_11_9_13_8_forest	control_fire_2_truck_2_2_pasture
Control_fire_1_truck_16_14_forest	control_fire_2_truck_12_15_forest	control_fire_1_truck_0_5_forest
move_2_truck_13_3_17_7_clearing	move_2_truck_12_15_13_14_forest	move_4_copter_8_4_4_2_forest
move_1_truck_16_14_20_12_forest	control_fire_2_truck_13_14_forest	move_3_copter_8_10_2_3_clearing

One difficulty arises. When LSA is used on text, cosines are easily understood since every reader has an intuitive experience of meaning (e.g., the sentences 'The man was driving a yellow car' and 'The man was traveling in a red car' have a cosine of .89, and our common sense tells us that these sentences convey similar information). When LSA is used on samples of performance from a *microworld*, there is no way the reader can understand the meaning of the log files without watching a replay or having an extraordinarily vivid imagination plus experience with the task. For most people, the following extracts in Table 3 are hardly understandable. For researchers familiar with *Firechief*, they should be as clear as a piece of sheet music to a musician. However, understanding the contents of these examples is not *conditio sine qua non* for understanding the advantage of LSA analysis over two other methods, namely exact matching and correlation between transition matrices. Suffice it to say that Examples 1 and 2 are very similar and Example 3 is very different from them. The attentive observer could induce this from the locations (coordinates in the *Firechief* map), the type of actions, and type of landscape cell. An *exact matching* method would count the number of times that the same action occurs in two examples. Then, the number of matches divided by the total number of actions in the example provides a measure of the similarity between two samples. This method would render a similarity of 1/8 between example 1 and 2, and zero in comparisons 1 vs. 3 and 2 vs. 3. This method is equivalent to keyword counting in text, which is known to be incapable of capturing similarities in meaning, because of the polysemy and synonymy effects discussed above.

A somewhat more flexible method is the use of *transitions between actions*, as proposed by Howie and Vicente (1998) and used in Quesada et al. (2000) and Cañas et al. (submitted). It is based on counting the number of times that one type of action precedes any other type. The frequencies of every transition are registered in cells in a table, and then the resulting tables for two examples are correlated. The method cannot account for all the variability in actions, because of the huge amount of zero entries that artificially

increase the correlation, so only action type was considered. This analysis is shown in tables 4(a,b,c). Since lots of information contained in the log files has been dropped, the method does not distinguish between these examples. The correlation between table *a* and *b* is 0.971; exactly the same correlation is obtained for tables *b* and *c*, and the comparison between *a* and *c* is 1 since the sequence of *type of action* is exactly the same. Thus, this method is seriously flawed because it yields implausible similarity estimates.

Finally, let us look at the results of similarity estimation using LSA cosines. The vector representing the sample has been calculated as the average of the 8 action vectors. Example 1 vs. example 2 has a cosine of 0.721, a high similarity value. Even though these samples share only 1/8 of the actions, LSA has correctly inferred that the remaining actions, although different, are functionally related. Comparisons between 1-3 and 2-3 have cosines as low as 0.050 and 0.071 respectively, showing that these action sequences are different indeed.

Correlations between LSA and Human Judgment

More formal comparisons between the performance of LSA and human observers than mere plausibility judgments are also possible. The problem is that, contrary to what happens when one uses LSA to model text comprehension, it is not easy to find experts in the task at hand. Everybody is a good example of the expert reader, but few people are expert in controlling the particular dynamic system called *Firechief*. To test our assertions about LSA, we recruited 3 persons and gave them extended practice, so they could learn the constraints of the task.

After 24 practice trials, these participants were used to assess the external validity of LSA similarities. Using *Firechief's* replay option, participants had to watch 7 pairs of trials (at a pace faster than normal) and express similarity judgments about these pairs. People watched a randomly ordered series of trials, in a different order for each participant, which were selected as a function of the LSA cosines (pairs A, B, C, D, E, F, G with cosines 0.75, 0.90, 0.53, 0.60, 0.12 and 0.06 respectively). One of the pairs was presented twice to measure test-retest reliability. That is, for example, pair G was exactly the same as pair A for

one participant, the same as pair F for another participant, etc. All the possible stimulus pairs were presented to each participant. Participants had to answer which pair seemed more similar. For example, LSA would say that pair B is more related than pair C, since the cosines are 0.90 and .53 respectively.

LSA cosines predicted human similarity judgments quite well. For 3 participants in this pilot study, the proportion of agreement LSA-human was 6/19, 14/19, and 13/19 respectively. Participants with strong agreement with LSA also showed more consistency in their judgments, that is they answered to the repeated item in the same way. The participant who had low agreement with LSA had performed poorly on the repeated item, which suggests that she may not have learned enough about the task or was not paying sufficient attention. Even so, the average agreement between LSA cosines and human judgments was 0.57, far superior to the agreement expected by chance, $0.5 \wedge 19 = 2e-5$.

Conclusions

LSA seems to be a promising new way of approaching Complex Problem Solving performance that overcomes some of the known limitations of previous methods. Apart from the features listed in the introduction, there are some additional pragmatic LSA advantages worth noting: (1) Since the basic unit of analysis is the token (action or state), even systems that are described in terms of nominal (discrete) variables can be analyzed. Both actions and states can be used as units. (2) The semantic matching mechanism permits discovery of similarities beyond simple coincidence in the log files containing actions or states. That is, participants who are using different interventions to realize the same strategy will be considered similar even if their log files share no actions (or states). (3) The level of granularity (whether we are working with individual tokens, slices of performance, whole trials, or collections of trials) need not be defined *a-priori*. Since every object, from one token to the participant's whole performance, can be represented as a vector in the high-dimensional problem space constructed by LSA, analyses can be performed at any level of detail.

There are, however, a number of limitations to the proposed method: (1) A huge sample of data is needed to construct

Table 4: Transitions between actions considering type of action only as described in Quesada et al. (Quesada et al., 2000) and Cañas et al. (submitted), for the examples 1,2 and 3. Cells contain frequencies of the transition defined by its row and its column. For instance, the number 4 in the center cell in table 4a means that in example 1 the transition move-move has appeared four times.

(a) Example 1			
	drop	move	Control
Drop	0	0	0
Move	0	4	1
Control	0	1	1

(b) Example 2			
	drop	move	control
Drop	0	1	0
Move	1	2	2
Control	0	1	0

(c) Example 3			
	drop	move	control
drop	0	0	0
move	0	4	1
control	0	1	1

the problem space. (2) Order effects are not taken into account. This means that, for LSA, a trial where the tokens have been scrambled to a random order has exactly the same meaning as the original version. This is a serious but, as we have shown, not a fatal limitation, as long as LSA is used with care in CPS tasks. (3) Though the SVD analysis is common practice and can be found in several statistical packages, a powerful computer is needed to run large analyses.

Acknowledgments

Our acknowledgements to Tom Landauer for proposing interesting issues concerning the selection of the unit of analysis in Complex Problem Solving. We are grateful to Kim Vicente and John Hajdukiewicz for sharing experimental data and insightful discussions. Many thanks to Bill Oliver, who provided passionate methodological discussions and theoretical contributions. A Dynamical Connectionist Account of Conceptual Change

Athanasios Raftopoulos (raftop@ucy.ac.cy),
Andreas Demetriou (ademet@ucy.ac.cy)
Department of Educational Sciences, University of Cyprus
P.O. Box 20537, 1678 Nicosia, Cyprus.

Abstract

Conceptual change can be accounted for at various levels of explanation. The cognitive level (Marr's computational level), the representational (Marr's "algorithmic"), and the implementational level. In this paper, we offer a dynamical account of types of conceptual change at the representational level. Our aim is to show that some classes of neural models can implement the types of change that we have proposed elsewhere. First we briefly describe at the cognitive level certain types of change that purport to account for some of the kinds of conceptual change. Then we lay forth the framework of dynamical connectionism; we discuss the representational level realizations of the cognitive level and claim that these can be depicted as points in the system's activation landscape. We offer, third, a dynamical account of some types change and we claim that conceptual change can be modeled as a process of modification, appearance of new and disappearance of attractors and/or basins of attraction that shape the system's landscape. Finally, we discuss the kinds of mechanisms at the representational level that could produce the types of change observed at the cognitive level, as modeled by means of dynamic connectionism.

Introduction

Conceptual change can be accounted for at various levels of explanation. Following Marr (1980), one can distinguish between three levels: the *computational*, the *algorithmic*, and the *implementational* level of explanation of cognitive systems. We prefer the term "cognitive" to "computational", and the term "representational" to "algorithmic", since there are accounts of cognition that deny the algorithmic nature of mental operations.

At the cognitive level, one can discuss cognitive operations that apply to information-processing content (such as addition and subtraction), operations that apply to structures as wholes, such as differentiation or coalescence (Carey, 1985; Chi, 1992), or, conceptual combination, generalization and abduction, and hypothesis formation (Thagard, 1992). This level addresses the issue of the functions computed by the information processing system.

At the representational level one can examine the algorithmic processes that realize conceptual change at the

cognitive level by transforming representations, such as Newell and Simon's (1972) "problem behavior graph" in production systems. In the connectionist paradigm one can study the processes of the emergence of new attractors, and repositioning of points realizing representational states in high-dimensional state spaces (Horgan and Tienson, 1996), or the changes in the connection weights and network structure (Elman et al., 1996; Schultz et. al., 1995; Plunkett & Sinha, 1992).

In this paper, we will discuss a theory of different types of cognitive change and their implementation at the representation level. Our aim is to show how certain classes of neural networks could implement some of the types of change that the authors have proposed (Demetriou and Raftopoulos, 1999). First, we will summarize these types of change. In the second part we will sketch the framework for the dynamics of change, relying on the dynamical interpretation of connectionist networks to explore possible means of modeling the stipulated types. In the third part we offer a dynamical account of some types change and we claim that conceptual change can be modeled as a process of modification, appearance of new and disappearance of attractors and/or basins of attraction that shape the system's landscape. Finally, we discuss the kinds of mechanisms at the representational level that could produce the types of cognitive change.

To that end we will employ neural networks whose behavior can be viewed as falling under one or the other of our kinds of change, and describe the behavior that neural networks should exhibit if they are to implement type of change.

Types of Change

Demetriou and Raftopoulos (1999) previously published a theory of conceptual change that addresses the issue of how a learning system makes the transition from one state to another. The theory provides a detailed analysis of the types of change that are observed both in cognitive development and during learning. The types of change are summarized in Figure 1.

Fig. 1. The types of change

We will briefly present here *combination*, and *fusion*. *Bridging* is a class of types of change, whose unifying feature is that (a) two or more existing structures are brought together to bear on each other and form a more complex structure, and (b) after bridging the constituent structures retain their functional autonomy, even though they may have been modified. The blended structures may remain unaltered and the resulting structure(s) may retain the characteristics of the constituent structures (as when "striped" and "apple" are combined to produce "striped apple"). In this case, the type of change is *combination*.

Fusion differs from bridging in that the mapped structures do not retain their relative autonomy after the mapping; instead, they fuse to one of the existing structures, or form a new structure. An example would be the fusion of retrieval and counting strategies, which are involved in simple operations of addition and subtraction performed by children aged 4-6. After fusion, around the age 6-7, the predominant strategy is retrieval by rote memory (Siegler, 1996).

The Representational Level

We discuss here the way representations can be modeled as properties of cognitive systems. At this level one examines the mathematical implementation of the cognitive level. In other words, we examine the way cognitive states are represented and how they are transformed and processed by means of operations performed on data structures.

These transformations can be either algorithmic (determined by a set of rules that apply to discrete static symbols that are the representations of the system) or dynamical (determined by mathematical relations that apply to continuous variables and specify their interrelations and evolution in time). This is why we call these transformative processes mathematical-state transitions; they describe the way the system moves between points in its state-space. We will address the issue of change from the perspective of connectionist theory interpreted in a dynamical way. Thus, will assume that a cognitive system is associated with a dynamical system physically realized by a neural network.

Neural Networks as Dynamical Systems

Recurrent neural networks (Elman, 1990) with distributed representations and continuous activation levels can naturally be construed in a dynamical way. They can be described by means of the evolution of the activation values of their units over time. To be able to model growth and avoid problems of lifelong (mainly catastrophic interference), one needs to consider a special class of networks, namely adaptive or generative networks. These networks can modify their structure during learning by adding or deleting nodes and can change their learning rates.

The number of units of the network determines the number of dimensions of the state-space associated with the system. Their activation values constitute the actual position in the state-space of the system. Adding a time-dependent parameter yields the phase-space of the system. Both in state- and phase-space, one can represent all the possible states that a system can take in time. Hence, in the connectionist account, the states of a cognitive system are depicted by the sets of activation values of the units that distributively encode these states.

These activation values are the variables of the dynamical system and their temporal variation constitutes the internal dynamics of the system. In addition to the state-space of a system, an external control space is also defined. The external space contains the real-value control parameters that control the behavior of the system, i.e., the connection weights, biases, thresholds, and, in networks in whose structural properties are implemented as real-value parameters (Raijmakers et al., 1996), the structure of the system. In dynamical systems the fast internal dynamics is often accompanied by a slow external dynamics. The external dynamics consist of the temporal paths in the external control space. The external dynamics consist of the network's learning dynamics (the various learning rules) and the dynamics that determine structural changes, such as the rules for inserting nodes in cascade correlation and growing radial basis function networks.

When the network receives input, activation spreads from the input units to the rest of the network. Each pattern of activation values defines a vector or a point, within the activation space of the system whose coordinates are the activation values of the pattern. The activation rules determine the state transitions that specify the internal dynamics of the system, i.e., the functions of the evolution of the system in time. Thus, the behavior of such a system is depicted as a trajectory between points in the activation state space.

The activation rules, the number of units, the pattern of their connectivity, and the learning rate(s) of the network determine the architecture of the system. These factors are determined by its long-term history of experiences, since the class of networks discussed here may modify either their patterns of connectivity, as they learn, by adding nodes, deleting nodes, and sharpening their connections, or their biases and learning rates. The activation vectors and the behavior of the system evolve as a result of the synergies among the architecture of the network, the input it receives, and the previous activity of the network, under the control of the external dynamics.

The behavior of the system is a collective effect of cooperation and competition, (Kelso, 1995). The competition is due to the effort of the system to retain its current state in the face of incoming information. If this information cannot be assimilated by the system, then the weights of a network change and the network may alter its structure to accommodate the new input.

The activation states, in which a network may settle into after it is provided with an input signal, are the attractors of the system. These are the regions in state-space toward which the system evolves in time. The points in state-space from which the system evolves toward a certain attractor lie within the basin of attraction of this particular attractor. Thus, the inputs that land within the basin of attraction of an attractor will be transformed by the connectivity of the network so that they end up at this attractor where the system will settle.

Networks in which the outputs change over time until the pattern of activation of the system settles into one of several states, depending upon the input, are called attractor networks. The sets of possible states into which the system can settle are the attractors. If the network is used to model cognitive behavior, then the attractors can be construed as realizing cognitive states to which the system moves from other cognitive states that lie within the attractor's basin of attraction.

The signal of the input is transformed as it moves through the hidden units into an attractor pattern as follows: a given input moves the system into an initial state realized by an initial point. This input feeds the system with an activation that spreads causing the units of the system to change their states. The processing may take several steps, as the signal is recycled through the recurrent connections in the network. Since any pattern of activity of the units corresponds to a point in activation space, these changes correspond to a movement of the initial point in this state space. When the network settles, this point arrives at the attractor that lies at the bottom of the basin in which the initial point had landed. In this sense, the inputs fed into the system are the initial conditions of the dynamic system. Similarly to a dynamical system that settles into a mode depending on its initial conditions, a neural network settles into the attractor state in whose basin of attraction the input falls.

For instance, in a semantic network meanings of words are represented as patterns of activity over a large number of semantic features. However, only some of the combinations of semantic features are features of objects. The patterns that correspond to these combinations are the attractors of the network, which are points in the state space corresponding to the semantic features of the prototype of the object signified by the word. These attractors are the meanings of words.

The concepts "attractor" and "basin of attraction" suggest a way of simulating the classical notion of symbol. The attractor basins that emerge as the network interacts with specific inputs might be construed to have symbolic-like properties, in that inputs with small variations that fall within the same attractor basin are pulled toward the same attractor (or cognitive state) of the system. Thus, various

inputs (tokens) give rise to the same stable point of attraction, the attractor (type), which in this sense offers a dynamical analog of the classical symbol (Elman, 1995).

The dynamical "symbols", unlike the symbols of classical cognitivism, are dynamic and fluid rather than static and context independent. The dynamic properties result from the dynamical nature of the activations of associative patterns of units. As the network learns and develops, the connection strengths continuously change. The same happens when new units emerge and old units "die" and the system reconfigures to maintain its knowledge and skills. All these cause changes in the original pattern in which an attractor/symbol was created in the first place, and as a result, subsequent activations differ. The same effects are caused by the different contexts in which the "symbol" may be activated. This happens because connections from the differing contextual features bias the activation of the units of the original pattern in different ways emphasizing some feature of the pattern or other. Thus, the attractor/symbol is almost never instantiated with the same activation values of the units that realize it.

The activation state-space of a network is a high-dimensional mathematical landscape. The state transitions in such a system are trajectories from one point on to another. Attractors correspond to cognitive states and the activation pattern that realizes each state is a vector, or a point. Thus, cognitive states are realized by points on this landscape. Since the distributed encoding of a cognitive state does not involve all units of the system, there will be points on the activation landscape that will realize more than one cognitive states (the set of coordinates of a point may satisfy the partial coordinates given by several activation vectors).

During the phase of activation-value changes the system passes through various possible outputs. All these outputs can be viewed as lying on an energy surface. When the system passes through a certain output-state whose energy is not lower than the energies of the neighboring states, it goes through another phase of activation-value changes in order to reduce the energy of the output state. When it reaches a point at which all the neighboring states have higher energies, it settles.

These states of minimum local energy are the attractors and can be construed as valley bottoms on energy surfaces. Thus, attractors should be distinguished from the networks' outputs in general. Not all outputs are settling points. Attractors form a subset of the set of outputs of a network, in that they are those outputs at which the system can settle. When the input of the system is such that the activation state of the system lies within the walls of the valley, the system will settle at the attractor at its bottom. Hence, the valley is the basin of attraction that leads to the specific attractor-state of minimum energy. Since the network has many attractors and basins of attraction, their relative position shapes the relief of the activation landscape of the system.

Modeling the Dynamics of Cognitive Change

In this theoretical framework, cognitive change results from the molding of the activation landscape, as a result of changes in the weights and the architecture of the network,

as the network attempts to accommodate new input signals. The molding may result either in the emergence of new, and/or disappearance of old, attractors, or in the reshaping of the basins of attraction. This process corresponds to a trajectory on the activational landscape. The idea that change is to be modeled by means of transitions in the state space of a dynamic system is at the heart of dynamical theories of cognition. Transitions in the state space of a dynamic system substitute for the algorithmic syntactically governed transitions of cognitivism.

The relief of the landscape determines the trajectories that are allowed, and the possible transformations among cognitive states. Cognitive change, thus, depends on the activational landscape of the system that learns. When information enters, the system tends to assimilate it within the existing framework of knowledge, which, in neural networks, is determined by the connection weights and the architecture of the network, which, in their turn, distribute the points that realize cognitive states on the network's landscape. We have posited certain types of cognitive change. In what follows we will sketch their dynamic realization at the representational level.

Combination

This type of change involves the combination of structures in such a way that the existing attractors and the landscape's relief (their basins of attraction) of the system are not affected. The new structure is superimposed, as it were, on the constituent structures. Consider the networks that simulate learning to pronounce words and non-words (Plaut et al. 1996). These networks learn the pronunciation of both regular and irregular words, by building the appropriate attractors. The attractors of regular words consist of componential attractors, in which case the basin of attraction is the intersection of the sub-basins of attraction of the componential attractors. The exception words have their own attractors with a lesser degree of componentiality. Combination explains the ability of the network to learn the pronunciation of words and non-words, in that this knowledge is the result of the combination of the sub-knowledge encoded by the componential attractors, as is shown in Figure 2.

In this figure only two componential attractors are depicted, for onset and the vowel in the reduced two-dimensional activation space of the phonemic units of the network. The basins of attraction for the word "by" and the non-word "dy" are the intersections of the sub-basins for pronunciation of *b*, *d*, and *y*, that is, the regions in the state space in which these sub-basins overlap. The black circle is the attractor for the word *by*, and the striped circle is the attractor for the non-word *dy*. The trained network learns to pronounce words by applying its knowledge regarding the pronunciation of the parts of the words (and of the role of context in pronunciation when it comes to exception words). The reduced componentiality of the exception words is depicted by means of a deformation of the intersection of the salient attractors for the onset *d* and the vowel *o*. The componential attractors and their basins of attraction remain unaltered.

Figure 2. Componential attractors

After the new pronunciation is learned, the two basins change their relative positions so that they intersect. Their intersection (i.e., the pattern corresponding to both sets of features) forms a new basin, which is the area in which the two basins overlap. The appearance of a new basin of attraction represents the learning of a new concept. The new basin of attraction is superimposed onto the two intersecting basins. The basins of attraction (sub-basins) and the attractors do not change. Whatever input was falling within one of the two basins before learning, still does so after the network has learned the new concept. The only change after learning is that some inputs fall within both the new basin and the old basins of attraction. This is a result of the superimposition of the new basin of attraction onto the two sub-basins.

Fusion

Stable structures within the neural net can be thought of as attractor states. Thus, the activation pattern of the structure attracts all other activation patterns that are similar enough with it (that is, all activation patterns that fall within the basin of attraction of the attractor). As a network learns, a new attractor state may emerge, which swallows the attractors that existed before. This is what happens in fusion. The two initial basins of attraction are also swallowed by the new one, so that all patterns that were falling within the one or the other now fall within the new basin of attraction. The system undergoes a phase transition that can be described as a reverse Hopf bifurcation (Figure 3), in which two stable states (bistability) are fused and disappear, and one stable state emerges (unistability).

Figure 4 displays the phase transitions associated with the fusion of "counting from one" and "memory retrieval" strategies (used by 4-6 year old children in simple arithmetic tasks) to the "memory retrieval" strategy that becomes predominant between 6 and 7 years of age.

Figure 3. Fusion as an inverse Hopf bifurcation

The generative networks designed by Schultz et. al., (1995) to model a series of cognitive tasks simulate the variability of the strategies available to children. Networks at some stage of their training in the balance-beam tasks may "employ" two different strategies to solve the same problem and, as training continues, progress to using reliably the more advanced strategy. These networks implement "fusion", by moving from bistability to unistability.

Figure 4. Fusion of two counting strategies

Strong and Weak Cognitive Change

In this context of dynamical connectionism, cognitive change consists in changes in connection weights, the structure, and the learning rates of the network. In connectionist networks an individual's state of knowledge is determined by the weights of the hidden units. Cognitive representational change is regarded as the individual's actual path through the space of possible synaptic configurations, that is, as the transformations of the weight vector in an n -dimensional weight space, where n is the number of the weights.

The appearance of novel cognitive states, and thus, the appearance of new attractors and the disappearance of old ones, implies a change of relief in the network's landscape (molding). Since the relief depends on the structure of the network, that is, the number of nodes, their connectivity,

and the activation functions, its molding is the result of changes in the structure of the network. Networks evolve as a result of the system's effort to adapt to a new environment, by superimposing new representations to old ones. Thus, the system modifies the "knowing assumptions" that do not fit in.

The account of cognitive change at the representational level allows us to recast the discussion regarding strong and weak representational change in terms of dynamic systems theory. Whether a cognitive change is weak or strong depends on whether the new structure increases the representational resources of the system. Since representations are points in the state space of the system, the expressive contents of the system correspond to such points. If the relief of the landscape is such that the system cannot settle at a content realizing point, that is, if this point is not a possible attractor state, the content that is realized by this point is not within the expressive capabilities of the system. When changes in the relief render this point an attractor, the change is strong; it results in an increase in representational power.

But the mere appearance of an attractor does not necessarily imply that a radical change has taken place, that is, that this is a novel attractor state. This is so if the content realizing point that appears as a new attractor was in fact expressible within the system; that is, if the system could have settled at that point, even if it had not done so, up to that time. When the structures "striped" and "apple" are combined an attractor state "appears" and the system acquires the new concept of "striped apple". This "new" attractor is a region in the state space, which realizes the content "striped apple" and is superimposed on the attractors of "apple" and "striped". But this is not a novel attractor, because this content was already within the expressive power of the system, since the relief of the landscape was such that the system could have settled if fed with the appropriate input at this point. In other words, the "new" attractor was situated at a local energy minimum in which the system could have settled if it had been fed with the appropriate input (the experience of a striped apple). The attractor appears without the landscape being molded and this attractor is just the sum of information expressed by the other attractors, which remain intact. In this case, the ensuing change is weak.

Weak change refers to changes in the semantic content of representations, which broaden their field of application but do not increase the expressive capabilities of the system. Attractors are merely repositioned in the landscape, which means that the activation patterns that define them do change. Reposition of any content-realizing point is accompanied by changes in the activation values that constitute the point's activation pattern, and changes in its spatial relations with other content realizing points. Since semantic information in dynamic systems is captured by the relative positions of content realizing points, repositioning is accompanied by semantic change.

This scenario does not apply to the case of fusion. No mere intersection of existing basins of attraction or any simple repositioning, could accommodate the salient input. A reshaping of attractor basins is required, as well as the

disappearance of an older attractor and the emergence of a novel one. These changes mould the landscape.

Thus, when new information is learned with repositioning of attractors and basins of attraction, and attractors are preserved (though the slope of the basins may change, with some becoming steeper and others becoming less steep), the resulting change is weak. Updating the connection weights seems to suffice for this. If the change in weights does not suffice for learning, the landscape is molded by changes in the network's structure (Horgan and Tienson, 1996). This may induce the appearance of new attractors; since the attractors are points on the landscape, the appearance of new cognitive states realizing points on this landscape, and the disappearance of old constitute strong changes, since the content-expressive power of the system increases. This process may require structural, i.e., qualitative, change.

Mechanisms of Change

At the cognitive level, the main Piagetian mechanisms driving conceptual changes are assimilation, accommodation, and equilibration. It is time now to consider the mechanisms driving change at the representational level. In each of the types of change discussed previously the processes that lead to the change are the same, always reducing to quantitative and qualitative changes in connection weights and the architectural structure of the network. These processes cause the repositioning of existing attractors, the disappearance of old ones, the appearance of new ones, and changes in the basins of attraction that shape the relief of the landscape. It could hardly be otherwise. In connectionism the computational mechanisms are domain general, statistical learning mechanisms, based on brain-style computation, that is, (a) on the spreading of the activation of each unit to other units, (b) on the modification of the connection weights, and (c) on the modification of the network structure.

McClelland (1989) argued that Piagetian "assimilation" corresponds to the activation spread in a network when a signal is presented to the input units and propagates through the network causing the activation of its units. The alteration of the weights, as a result of the network's learning, models Piaget's "accommodation", that is, the change that the network undergoes trying to fit in new experiences. Shultz, et al., (1995), and others, have proposed networks that adapt their structure as they learn by increasing their hidden units to accommodate the demands of the task. They offer a variation of McClelland's account that is suited better for networks that can modify their structure. The quantitative phase of error reduction and weight change may correspond to Piaget's "assimilation" of information in a pre-existing structure, whereas the qualitative structural change corresponds to Piaget's "accommodation" of the system. Quantitative change renders possible knowledge acquisition within a fixed representational framework, whereas qualitative change allows an increase in representational power.

Abstract

In this paper we address the issue of grounding for experiential concepts. Given that perceptual demonstratives are a basic form of such concepts, we examine ways of fixing the referents of such demonstratives. To avoid 'encodingism', that is, relating representations to representations, we postulate that the process of reference fixing must be bottom-up and non-conceptual, so that it can break the circle of conceptual content and touch the world. For that purpose, an appropriate causal relation between representations and the world is needed. We claim that this relation is provided by spatial and object-centered attention that leads to the formation of object-files through the function of deictic acts. This entire causal process takes place at a pre-conceptual level, meeting the requirement for a solution to the grounding problem. Finally we claim that our account captures fundamental insights in Putnam's and Kripke's work on "new" reference.

Introduction

John Campbell (1997) claims that the problem of the reference of concepts is the problem of relating concepts with imagistic content. His 'imagistic content' is the content of our experiences as we consciously access it and use it to see things as 'being such and such'. The most basic form of reference is when one perceives a thing and refers to it on the basis of one's perception by using a demonstrative, such as, "that" or "this". The reference of such a perceptual demonstrative is determined by spatial attention.

Though Campbell's thesis regarding the importance of spatial attention and perceptual demonstratives in establishing the reference of concepts to spatiotemporal objects goes in the right direction, his account has some serious problems. The main issue we wish to take on here is his view that the matter of the reference of concepts is exhausted by relating propositional with pictorial content. The problem is that both propositional and experiential content are representations, while the issue of reference is supposed to be a matter of grounding representations to the world, not of relating representations of different kinds to each other. This classical threat of infinite regress is now known under the label of 'encodingism', the view that representations are connected with the represented entities via some kind of correspondence between the two (see the critique in Bickhard, 1993 and Christiansen and Chater, 1993). Solutions that propose some such correspondence that, in turn, stands in need of an 'interpretation' cannot answer the symbol grounding problem, since they fail to account for how "symbol meaning [is] to be grounded in something other

than just more meaningless symbols." (Harnad, 1990) The encoding of symbols in further symbols cannot be the solution.

We know that the problem has a solution since (some of) our concepts do have reference. A solution that does not fall into the trap of encodingism could be provided if we could single out a non-symbolic connection between our representations and the world. It seems plausible that such a connection is a causal one and that it would take place without the involvement of conceptual (i. e. symbolic) means. This is where Campbell has pointed in the right direction.

So, our task is to give a contribution to the problem how the concepts in the mind of a particular speaker can refer to objects in the world. How is it possible that I can use the concept "house" to refer successfully to certain objects? We need to single out a causal process, that could be a grounding for such reference (and that would not presuppose concepts). Once such a grounding is laid, the speaker can expand the initial grounding from experientially accessible kinds of objects to objects to which he has no such access (for contingent or principled reasons, as in the case of abstract objects). Each use of a concept would depend on such a grounding through a causal chain, starting from the initial grounding(s). How the grounding of non-experiential concepts takes place is not discussed in this paper.

In this paper we argue that spatial attention and/or object-centered attention establish the referents of certain kinds of concepts, namely perceptual demonstratives. Demonstratives are a promising start because they might rely on bodily movements in a context, not on conceptual entities that would require an interpretation. We first discuss these forms of attention and the way they individuate objects, arguing that spatiotemporal information individuates the referents and that this can be done in a bottom-up, non-conceptual way.

Then we employ Garcia-Carpintero's (2000) and Devitt's (1996) theory of demonstratives to show how the senses of demonstratives individuate their referents (demonstrata). We claim that the senses of demonstratives use the spatio-temporal information contained in the object files to fix reference. The non-conceptual use of this information provides the causal relation that grounds representations in the world. To explain how individuation takes place we employ Ballard et. al.'s (1997) theory of deictic codes and Kahneman and Treisman's (1984) theory of object-files.

Finally, in the third part of the paper, our thesis regarding reference is discussed in the context of Putnam's (1975, 1983; 1991) and Kripke's (1980) "new" theory of reference. We claim that the notion of an object-file containing predominantly spatio-temporal information provides the causal connection with the world that Putnam and Kripke sought to establish. We discuss the grounding of concepts whose referents are the basis of one's perception when one uses a demonstrative. In this sense the solution provided here, even if successful, is only the first step toward solving the problem of concept grounding in general.

Individuating Objects

Campbell (1997) argues that object individuation takes place by means of selective spatial attention that picks out objects features, forms feature maps, and integrates those that are found at the same location into forming objects in the way described by Treisman's *Feature Integration Theory (FIT)*. In vision, information from different feature maps is bound together by extracting the location encoded implicitly in any feature information. Spatial attention makes the implicit location explicit. Information localized at the same location is bound together and thought to pertain to a certain object that occupies that space.

FIT belongs to a family of theories that hold that when one attends to an object then one automatically encodes all of its features in visual working memory. Against this, there is evidence for the existence of object-based attention which overrides featural information (other than spatiotemporal information) and which on certain occasions may pick out objects without any regard even for spatial information (Scholl & Leslie, 2000; Scholl, 2001). The role of object centered attention is primarily the parsing of a scene into discrete persisting objects, and the selection of some among these objects. The same evidence suggests that selection based on spatio-temporal information occurs very early in information processing (though segmentations of a scene into various discrete objects probably occurs at all levels of vision); in the case of vision it takes place in mid-level vision. Mid-level vision is bottom-up and cognitively impenetrable (Pylyshyn 1999; Raftopoulos, 2001), i. e. not accessible to conscious cognition, so it is not conceptual. In other words, some form of the selection of objects and the parsing of a scene is a bottom-up, cognitively impenetrable process (Carey and Xu, 2001; Scholl, 2001). Such a process would be a good candidate for the causal process we are looking for.

Given the pre-conscious processes in mid-level vision, we need to distinguish two steps: 1) *object individuation*, the processes that selects objects as discrete entities that persist in time, and 2) *object identification*, the processes that lead to the representation of objects under a certain description. The latter involves a strong semantical component, in the sense that the object represented has been identified as being such and such (e. g. a house). The former involves a much weaker level of representation. It purports to convey the sense that an object file has been opened for that specific object, that is, that the object has been "catalogued" or "indexed" as *something* that exists and persists separately of other objects with its own continuous spatio-temporal his-

tory – not as something that has certain properties (such as that of being a house). Object-files are allocated and maintained primarily on the basis of spatiotemporal information. Objects can be parsed and tracked without being identified. This representation allows access to the object but it does not describe the object. Object individuation does not require the existence of a concept associated with that object. (Of course, in theory successful object identification could also be used for individuation, as in definite descriptions like "the large house with the porch", but this presupposes grounded symbols, so we are interested in the inverse: individuation without identification.)

As an example for object individuation, think of two identical red squares that are situated in different locations. Since they are identical with regard to their features, the only way they could be treated as two distinct objects is by considering their spatiotemporal history. This presupposes that there is an object-centered attentional mechanism that is sensitive only to spatiotemporal information and not to feature information, which can pick up these objects by opening object-files. Precisely this conclusion is reached in the *MOT* (Multiple Object Tracking) experiment (Pylyshyn & Storm, 1988). In these experiments subjects must track a number of independently moving identical objects, that are initially tagged by attentional cues, among identical distractors. The success in *MOT* presupposes that the subjects attend to spatiotemporal information (relative location and direction of motion) and not to features, such as color and shape, or even the actual location of the objects. One could say that the attentional cues individuate/index in parallel the targets by assigning them tags that the subject can follow afterwards through motion. Thus, this mechanism individuates these objects and allows the subject to follow their paths and transformations while maintaining their identity as distinct objects.

Carey and Xu (2001) argue that a mechanism tracking the spatiotemporal history of objects precedes feature tracking mechanisms, and that this mechanism may override conflicting featural information. In other words, object individuation precedes feature identification – as we said above. The cognizer does not "know" or "believe" that an object moves in continuous paths, that it persists in time, though it uses this information to index and follow the object. She does not encode the object's features in some concept. She may not even have acquired the concept "object" (in this sense, you can see a house without having the concept of "house"). Object individuation may eventually result in the belief that an object is here or there, but this indexing itself does not appeal to some stored concepts regarding objects. Hence, if object individuation establishes reference, then the reference of demonstratives is not determined by a set of descriptions of features.

The discussion of object based attention shows that object files are opened and maintained on the basis of spatiotemporal information by means of cognitively impenetrable mechanisms. Petitot (1995) talks of the "positional (local) content-structure" of the scene. This positional structure is nonconceptual, and conveys information about nonvisual properties, such as causal relations (e.g., *X* "transfers" something to *Y*). In this latter category one can include the

functional properties of objects, referred to as 'affordances' of objects. Suppose that one witnesses a scene in which *X* gives *Z* to *Y*. The semantics of the scene consists of two parts: (i) the semantic content of *X*, *Z*, *Y* and "give" as a specific action, and (ii) the purely positional local content. The latter is in fact the image scheme of the "transfer" type. *X*, *Y*, and *Z* occupy a specific location in the space occupied by the scene. In the image scheme, *X*, *Y*, *Z* are thus reduced to featureless objects that occupy specific relative locations, and in that sense can be viewed as pure abstract places. More specifically, *X*, *Y*, and *Z*, which in a linguistic description of the scene are the semantic roles, "are reduced to pure abstract places, locations that must be filled by 'true' participants." These places are related by means of an action, of a "transfer" type.

Petitot's "places" do not refer to the actual locations that are occupied by the objects in a scene. What Petitot seems to allude to using the spatial metaphor is the notion of an object devoid of all features (including actual location), except that it persists in time, and occupies some space – similar to the talk of "two-place predicate". It is this individuation of an object that Petitot seeks to describe by saying that the objects' only property is that they occupy their own space and this is what the notion of objects as "pure abstract places" purports to convey. In this framework, the concepts that are used in the linguistic descriptions of a scene are locational configurations, that is, spatial structures. Petitot describes the routines and algorithms of early vision that might retrieve from the morphology of a scene in a bottom-up manner the global positional information contained in it.

Several theories of mechanisms of object indexing (what we call "individuation") have been proposed. They include the *FINST* theory of visual indexing (Pylyshyn, 2001), the object-indexing theory (Scholl & Leslie, 1999), the object-files theory of Kahneman & Treisman (1984) and more recently Ballard's et. al., (1997) theory of deictic codes. The common thread of these theories is the claim that there exists a level of (visual) processing in which objects present in a scene are parsed and tracked as distinct individual objects without being recognized as particular objects that are such and such. Thus, they stress the point that object individuation precedes object identification and that there is a level of object representation that does not encode features and does not presuppose concepts; a preconceptual level of object representation. We have already discussed «object-files». We are now going to describe a plausible mechanism that allows object individuation and tracking.

Deictic Codes, Object Individuation and Tracking

A recent theory of deictic pointers has been developed by Ballard, et. al., (1997). They claim that at time scales of approximately 1/3 of a second, orienting movements of the body play a crucial role in cognition and form a useful computational level. At this "embodiment level," the constraints of the physical system determine the nature of cognitive operations. "The key synergy is that at time scales of about 1/3 of a second, the natural sequentiality of body movements can be matched to the natural computational economies of sequential decision systems through a system of implicit

reference called deictic in which pointing movements are used to bind objects in the world to cognitive programs."

Our discussion revolves around the issue of relating internal representational states with the world. We have emphasized the potential role played by non-conceptual processes in mediating the relation between representations and the world. Now, as we mentioned, the shortest time at which bodily actions and movements, such as eye movements, hand movements, or spoken words, can be observed is the 1/3-second-time scale, the embodiment level. Thus, the mechanisms that relate conceptual content with the world through action must be sought at this level. Suppose that one looks at a scene and selects a part of it through eye focusing. The brain's representation is about, or refers to, that specific part of the scene. Acts such as the eye focusing are called "deictic strategies", from the Greek word 'deixis' (pointing at), since they are analogous to pointing with one's hand. When one's internal representation refers to an object through such a deictic representation, this is a "deictic reference."

Eye fixation exemplifies the role of deictic mechanisms, or pointers, as grounding devices, that is, as devices that ground internal representations and cognitive programs to objects in the world, through deictic reference. This binding is implemented by two functional routines in the visual system. When a scene is perceived, the eye movements perform two main functions; they extract properties of pointer locations (object identification) and they point to aspects of the environment (object localization). The second task is that of our object individuation.

Perceptual Demonstratives and Reference

Let us start by having a brief look at the three most influential accounts of demonstratives. The standard Fregean analysis of demonstratives considers them similar to definite descriptions and assigns them a reference (*Bedeutung*) and a sense (the mode of presentation of the referred object). Frege's senses are descriptive, in that they provide descriptions in terms of features of the singular term. However, demonstratives do not function quite like definite descriptions do, since demonstratives and indexicals in general are rigid designators (Kripke, 1972) whereas definite descriptions are not. A token of "that house" refers to the salient house, while "the largest house in town" may refer to one house today and to another next year. This has been used to argue that the senses of demonstratives, if any, are not descriptive. Below, we will argue that the 'senses' of demonstratives consist in causal chains that ground them in the world (a thesis similar to that of Devitt, 1996, Kripke, 1980 and Putnam, 1975; 1991). The causal chains start with a direct perceptual encounter with an object, an encounter that grounds the demonstrative in the world. Devitt (1996, 164) calls such an encounter a "grounding" – and we shall use this for the "grounding problem".

We join Garcia-Carpintero (2000), and Devitt (1996) in the view that the difference between definite descriptions and demonstratives does not discredit the role of senses of demonstratives in determining their content. Our thesis is that the content or meaning of a demonstrative consists both of its referent and its sense. This is the second main account

of demonstratives. We will not argue in favor of this view, though, because it is really not crucial to the main argument developed in this paper, namely that reference construed as object individuation can be fixed by means of bottom-up perceptual processes that involve non conceptual content. What is important to this argument is the existence of such a process; this claim is independent of whether the referent is part of the meaning of demonstratives. The argument, however, as we shall see, essentially involves the role of the mode of presentation of a demonstrative in individuating objects. Thus, our claims go against the third important construal of demonstratives.

This is the direct reference theory, according to which the only content of a demonstrative is its denotation, or in other words, that the only linguistic function of a demonstrative is that it refers to its demonstratum, its referent (Kaplan, 1989). It does not have a sense. Paraphrasing Kaplan's (1989) account of the theory, one could say that a demonstrative does not describe its referent as possessing any identifying properties, it only refers to it. Though we agree that demonstratives do not provide identifying descriptions of their referent, we argue that they allow the individuation of the referent as a singular persisting object, by means of object-centered attention and spatial attention. These two provide the causal chains that ground the demonstrative. Thus, the mode of presentation of a demonstrative is not descriptive but causal. They can do that because they have a mode of presentation of the referent. But what is the mode of presentation when one says for example "that" pointing to a house?

Campbell (1997) thinks that the problem of the sense of a perceptual demonstrative is a problem about selective attention, in so far as he considers the mode of presentation to provide imagistic information related to the referent. It is the role of selective spatial attention to isolate that information in a scene that pertains to the referent. Thus, Campbell takes the mode of presentation of a demonstrative to include information that could individuate the referent on the basis of its observable features and, in an essential manner, on the basis of its spatial location. In fact, difference of location only suffice to establish difference in the mode of presentation of the same object by two different demonstratives.

Garcia-Carpintero (2000) and Devitt (1996) offer a thorough account of the senses of demonstratives, which is similar in some respects to that of Campbell's. The sense, according to Garcia-Carpintero, is an ingredient of presuppositions of acquaintance with the referent; "presuppositions" meaning "propositions that are taken for granted" when a statement is uttered. In this fashion, senses are individuating properties that allow the individuation of the referent.

Suppose one perceives something as being a house and utters the statement "that is *f*" pointing at a certain object (the house) and assigning it the property *f* (e. g. "beautiful"). The term "that" is a singular term associated with the description "the *f* house". According to Garcia-Carpintero, when one uses the singular term "that" one takes oneself to be acquainted with an object by having a 'dossier' for "the *f* house", which picks it out. The object fulfills the conditions specified in the dossier, in our case the proposition "there is

a unique house most salient when the token *t* of 'that' is produced and *t* refers to that house." Now, the phrase "most salient when *t* occurs" is equivalent to the expression "house in such and such a location with such and such visual features." The "in such and such a place with such and such visual features" is the mode of presentation of the token *t* of the demonstrative "that". This mode of presentation individuates the object to which the demonstrative refers.

The dossier of the object that acquaints one with the object can be updated by new information, by adding contents or by revising its content. One notes a distinction between an object being singled out as the referent of a demonstrative and its acquaintance dossier (file). The latter ontologically presupposes the former; one needs an object to create its dossier. One also needs to ensure that the object with such and such features at time *t*₁ is the same object with such and such features at time *t*₂. Perception must provide for a mechanism that establishes the existence of an object as a distinct entity and opens a dynamic file on it. One needs, in other words, a mechanism that individuates the demonstrata of perceptual demonstratives.

Object Individuation and Reference

Let us see where we stand with regard to the issue of the reference of perceptual demonstratives related to object individuation. When one uses a demonstrative one opens a file for the object being demonstrated. According to the psychological evidence, the first thing that this file does is to individuate the object based on spatiotemporal information. This ensures the existence of a distinct object whose paths in space and time can be tracked. The object file thus allows acquaintance with the referent of the demonstrative, and in this sense, it constitutes its mode of presentation. Kahneman's "object-file" becomes a truncated version of Garcia-Carpintero's "dossier", a dossier that contains only spatiotemporal information. As the object moves in space-time, feature detection mechanisms infuse the file with feature information allowing feature identification (the full "dossier").

Let us investigate the power of the account sketched so far with Brian Loar's (1976) example, also used by Garcia-Carpintero (2000) to argue that descriptive senses fix the referents of the terms with which they are associated: Suppose that Smith and Jones see a man on the train every morning. One evening they watch a man being interviewed on a television show, they are unaware that this man is the same man they meet on the train every morning, and it so happens that during the show they have just been talking about the man on the train. Suppose now that Smith switches his attention to the man on the television and says, "he is a stockbroker", referring to the man on the television. Jones, unaware of Smith's attention switch, takes Smith to refer to the man on the train about whom they have been talking. Though Jones has correctly identified the referent, since the man on the train is the same as the man on the television, one feels that Jones has failed to understand Smith's utterance. This shows that the manner of presentation of singular terms is important even on referential uses for grasping the meaning of what is being communicated.

The upshot of Loar's example is that although Jones' belief to the effect that the man on the train is a stockbroker has the same truth conditions as Smith's belief that the man on the television is a stockbroker (since the referent in both beliefs is the same person), Smith is justified in holding his belief, whereas Jones' is not.

Jones missed the information that would have justified his belief, because he does not know that the man on the television and the man on the train are the same person. So, for Jones, and thus information pertaining to the former does not apply to the latter. To use the terminology of this paper, Jones has two different object-files; one for the person on the television and one for the person whom he meets on the train. The role of the mode of presentation of a singular term is to clarify this point, namely whether the object under consideration has been individuated the appropriate way. Spatiotemporal information purports to do exactly that: had Jones followed the spatiotemporal path of the person on the train, he would have known that it is the same person that appears on the television and he would have used all relevant information to update that person's object-file; so his belief would have been just as justified as Smith's.

It seems thus, that object individuation (the mode of presentation) is indispensable to fixing the referent of a perceptual demonstrative. The individuation is accomplished by opening an object-file fixing the object to which the demonstrative refers and allowing its tracking. In the course of tracking, additional information, e. g. on shape and color, may be added to the "dossier" to allow tracking in difficult circumstances (as when one thing is inside some other thing). It is essential for the success of concept grounding and the escape from the regress of encodingism that this individuation process is not cognitively penetrable. No conceptual content, no existing representations can be used in the individuation process, so it has to be inaccessible to conscious content-laden processing. Also, individuation should not be seen as establishing a concept – this is what happens in the step of identification. Individuation just grounds the concept, fixing it onto an object so that the concept can be "filled" with information.

New Theories of Reference

If object individuation can fix reference and if object individuation can be carried out without conceptual involvement, then reference can be fixed in a nonconceptual manner. Of course, this goes against the standard descriptive theories of reference, according to which a sign is associated with a concept in the mind, a "sense", which constitutes its meaning and determines what the sign refers to. It allows one to pick out the objects in the environment that are 'fall under' the concept. The reference of a word is fixed by certain of the descriptions associated with the word: that thing over there counts as a "house", given that it is a building which could be used as a human dwelling.

A problem with these kinds of theories has been expressed in terms that remind strongly of the symbol grounding problem: Devitt (1996, 159) argues that descriptive theories of reference are incomplete because by explaining references by descriptions, they appeal to the application of descriptions of other words; thus, they explain ref-

erence by appealing to the reference of other words. To escape the lurking infinite regress, there must be some words whose reference does not depend on that of other words, that is words that are founded directly in the world.

Kripke (1972) and Putnam (1975; 1983; 1991) have argued that the standard conception of reference fails for certain kinds of words, namely demonstratives, proper names and natural kind terms. It is interesting to see whether our notion of reference is compatible with Putnam's (1975; 1983) direct-reference theory ("direct" in that it avoids the mediation of conceptual content in establishing reference). According to this theory, descriptions ascribing properties would identify the wrong referents of the terms. Once a causal contact between concept and object is established, the world itself has a say on the fixing, what Putnam (1991) will later call the "contribution of environment".

Putnam (1991) argues that there is an indexical (deictic) component that participates in reference fixing. When one takes a liquid sample to be water, one does so because one thinks that this liquid sample has a property, namely, "the property of behaving like any other sample of pure water from our environment" (Putnam 1991, 33). This property is not a purely qualitative property (meaning that membership is not determined by a set of criteria); its description involves a particular example of water, one given by pointing or focusing (hence, the term "indexical"). The stuff out there, to which the act of pointing is an essential part of fixing reference of the natural kind term "water", is the contribution of the environment. Putnam says that "... the extension of certain kinds of terms ... is not fixed by a set of 'criteria' laid down in advance, but is, in part, *fixed by the world*. There are *objective laws* obeyed by multiple sclerosis, by gold by horses, by electricity; and what it is rational to include in these classes will depend on what those laws turn out to be." (Putnam 1983, 71). This brings into mind the notion of causal chains by means of which demonstratives refer, causal chains that are established through object based and spatial attention.

Kripke (1980) refers to this assigning of names as "initial baptisms". Suppose, that one points to a star and says, "that is to be Alpha Centauri" (Kripke, 1980, 95). By this one commits himself to the following: "By 'Alpha Centauri' I shall mean that star over there with such and such coordinates." Kripke (1980, 135) claims that the reference of general natural kind terms is similarly fixed: "the reference (of singular terms) can be fixed in various ways. In an initial baptism ostentation or a description typically fixes it. ... The same observation holds for such a general term as 'gold'."

These are telling examples, because they point out the role of spatial information and of object based attention in fixing the reference of singular terms. The causal chain that grounds the term starts with spatio-temporal non-descriptive information that opens an object-file for some object. This way of fixing the referents of singular and natural kind terms captures adequately Kripke's intuition that: "Don't ask: how can I identify this table in another possible world, except by its properties? I have the table in my hands, I can point to it, and when I ask whether *it* might have been in another room, I am talking, by definition, about *it*. I don't have

to identify it after seeing it through a telescope. If I am talking about it, I am talking about *it*." (1980, 52-53). Though Kripke speaks of proper names, his analysis easily transfers to all singular terms, and thus, to perceptual demonstratives (Garcia-Carpintero, 2000). Names and indexicals, are associated with something extralinguistic, their referents. Some existentially given thing is essential in fixing these referents.

We have claimed that the mode of presentation of the referent by its demonstrative is essential in reference fixing, and we have argued that the mode of presentation fixes reference by opening an object-file for the referent of the demonstrative. This object-file includes spatiotemporal information and its function is to individuate the referent, that is, to establish the existence of a distinct body that perseveres through space and time. It establishes the causal continuity with the thing originally "pointed at" by the perceptual demonstrative, satisfying Putnam's criterion for reference fixing. It also provides the causal relation between the representation and the world that grounds the former in the latter. The object-file provides the indexical component that participates in reference fixing. The content of the object-file being retrieved in a bottom-up manner warrants that this object file is the 'contribution of the environment' and not the contribution of conceptual content.

Conclusion

We argue that perceptual demonstratives capture the essential way in which one refers to objects in one's experience. The sense of "demonstrative reference" involved, however, departs from the notion of the referent as an object that is individuated by some description. The representation of the referent in the sense intended here does not encode any featural properties, is pre-conceptual, and the process that leads to its formation is cognitively impenetrable. The only property that the individuated referent has is that it is being tagged as a discrete object that persists in time and occupies some space, and thus, is being rendered accessible to the viewer. We claim that this process of reference fixing provides the causal relation required to solve the grounding problem.

When the fly flied and when the fly flew: the effects of semantics on the comprehension of past tense inflections

Michael Ramscar (michael@cogsci.ed.ac.uk)

Division of Informatics

University of Edinburgh, 2 Buccleuch Place

Edinburgh, EH8 9LW, Scotland.

Abstract

Although previous theories of past-tense verb inflection have considered phonological and grammatical information to be the only relevant factors in the inflection process (e.g. Bybee & Moder, 1983; Rumelhart & McClelland, 1986; Kim, Pinker, Prince & Prasada, 1991), Ramscar (in press) demonstrated the importance of semantics in processing inflectional morphology. This paper presents an experiment that demonstrates the on-line effects of semantics on inflection. These findings indicate that regular and irregular inflections are determined by semantic and phonological similarities in memory, and furthermore that people are not responsive to the kind of grammatical distinctions amongst verb roots that default rule theories of inflection (Pinker, 1999) presuppose.

Introduction

In most theories -- and studies -- of past-tense verb inflection, phonological and grammatical information have been considered to be the two relevant factors in the inflection process (e.g. Bybee & Moder, 1983; Rumelhart & McClelland, 1986; Kim, Pinker, Prince & Prasada, 1991; Pinker, 1991; 1999). However, in some models of inflectional processing (MacWhinney & Leinbach, 1991; Joanisse & Seidenberg, 1999), semantic processes have been included to help explain the processing of homophone verbs (e.g. *brake/break*). Since *brake* and *break* both sound the same, phonology alone cannot distinguish which of *broke* or *braked* is to be the correct past tense form for the input *breɪk*.

Although using semantic information to guide this process appears intuitively plausible, this suggestion has been fiercely criticised by Pinker and colleagues (Kim et al, 1991; Pinker, 1999), who put forward an alternative, nativist account of homophone inflection (Pinker, 1991; 1999). This predicts that the regularisation of irregular sounding verb stems is driven by innate grammatical sensitivity: verbs that are instinctively perceived to be denominal will be automatically regularised. This account was supported by results reported by Kim et al (1991) which indicate that grammatical factors correlate better than semantic factors with people's ratings of the acceptability of past tense forms in context, although these results did not rule out any semantic role in inflection.

However, a recent series of experiments, Ramscar (in press) has demonstrated that the assumption that inflection is driven purely by grammar and phonology is flawed. A series of elicited inflection tasks showed that the semantic context in which a novel verb occurred influenced the forms participants later produced to mark the past tense of that verb. If participants first encountered the novel verb *sprink* in a context that involved consuming large quantities of fish and vodka (semantically similar to *drink*), they were likely to produce an irregular past tense form for it (*sprank*). But if they first encountered *sprink* in a context which presents as a verb to describe symptoms associated with a disease that involve rapid movements of the eyelid (semantically similar to *blink*), they were likely to go on and produce a regular past tense form (*sprinked*). Further, a comparison of the forms participants produced for the nonce verbs *sprink* and *frink* in a sparse, 'neutral' context (70% irregular) to those produced in the context involving rapid movements of the eyelid (70% regular) showed that the production of regular past tense forms increased when the semantic similarity between *sprink* and *frink* and the regular verbs *blink* and *wink* was increased. From these results it appears that not only irregular forms can be produced by analogy, but regular forms as well.

Semantics versus grammar in homophone inflection

Evidence that semantics affects inflection offers a solution to the homophone problem: different forms of homophone verbs are distinguished and computed by reference to their different meaning. Further, Ramscar (in press) contrasted the semantic account of homophone inflection with a nativist attempt to solve this problem put forward by Pinker and colleagues (Kim et al., 1991; Pinker, 1991, 1999, 2001) which predicts that the regularization of irregular sounding verb stems is driven by innate grammatical sensitivity: that any verb that is *perceived* to be denominal will be automatically regularized, resulting in different inflection patterns for denominal verbs that are phonologically identical to irregular deverbal verbs. Ramscar (in press) found that participants' sense of the semantic similarities between verb forms correlated strongly with participants preference for a regular or

irregular past tense form of a homophone verb in context (after partialling out the effects of grammar, $r=.723$), whereas participants' perception of the grammatical origins of verbs correlated poorly with their references for irregular versus regular past tense forms (after partialling out semantics, $r=.066$). Further experiments showed that on both nonce and existing verbs, if the semantics of the verb were similar to those of an existing phonologically similar irregular, participants would favor irregular inflections even when they perceived the verbs to be denominal. Ramscar (in press) concluded that in fact, the grammatical origins of verbs had no effect on inflection, which was entirely governed by phonology and semantics.

One or two routes to inflection?

A further implication of these findings is that they undermine the one in principle objection to modeling past tense inflection using a single mechanism (Ramscar, in press). Pinker and colleagues (e.g. Pinker & Prince, 1988; Pinker, 1991, 1999, 2001) have claimed that the systematic regularization of verbs based on nouns would require two mechanisms for determining inflections, one method using phonological analogy (to explain cluster effects in inflection, resulting in forms such as *spling/splang*), and another method using grammatical information (i.e. a rule) to explain how verbs based on nouns are automatically regularized. The findings that semantics is used to distinguish homophone verbs and that the grammatical origins of verbs do not determine their past tense forms (Ramscar in press; see also examples such as *shoe/shod* versus *shoo/shooed* where the denominal verb is the irregular) obviate any *requirement* for models to account for this second, grammatically determined method of inflection.

Since it appears that single-route models *may* be entirely capable of modeling inflection patterns based on phonological and semantic properties (see e.g. MacWhinney & Leinbach, 1991; Joanisse, & Seidenberg, 1999) it appears that Rumelhart and McClelland's (1986) claim that single-route accounts provide "a distinct alternative to the view that children learn the rules of English past tense acquisition in any explicit sense..." merits further investigation. As Pinker (1991, 1999, 2001) has argued, the peculiarities of the irregular past tense system are best explained by an associative system based on analogy to stored forms, and not by rules: but if regular and irregular past tense forms *are* produced by the same mechanism – based on semantic and phonological analogy – then it may well be that learning the English past tense really does not involve acquiring a rule in any explicit sense.

The experiment described in this paper was designed to further probe this question. It was designed to examine the way in which semantics affects the comprehension of existing past tense forms. The dual-route model of past-tense inflection claims that regular inflection is unaffected by meaning or associative

factors in memory (Pinker, 1991, 1999, 2001). In this experiment the meanings of existing verbs were manipulated to examine the effects of this on both their regular and irregular forms.

Experiment 1

This experiment was designed to test whether meaning has an effect on the comprehension of past tense verb forms by measuring the reading-times of regular and irregular forms of existing verbs in different semantic contexts. The dual-route model of inflectional morphology claims that the processing of regular past-tense inflection is unaffected by meaning or associative factors in memory:

"[Regular inflection] is modular, independent of real-world meaning, non-associative (unaffected by frequency and similarity) sensitive to abstract formal abstractions (for example, root versus derived, noun versus verb), more sophisticated than the kinds of "rules" that are explicitly taught, developing on a schedule not timed by environmental input, organized by principles that could not have been learned, possibly with a distinct neural substrate and genetic basis." (Pinker, 1991, p. 534; see also Pinker 1999, 2001)

Accordingly, the dual-route predicts that semantic factors can only affect the comprehension of irregular forms. In line with the findings of Ramscar (in press, Experiments 2, 3 and 4), where semantics appeared to affect regular production, it was expected instead that semantics would affect the comprehension of all simple past tense forms. The contrasting single-route prediction tested here was that a regular past-tense form should be easier to read in a context that is semantically dissimilar to the ordinary usage of a phonologically identical irregular verb and an irregular past-tense form should be easier to read in a context that is semantically similar to the ordinary usage of a phonologically identical irregular verb.

Participants

Participants were 36 undergraduate students from Edinburgh University. All participants took part voluntarily in the study.

Materials

Four sets of materials examined four existing verb forms (*sink, fly, drink* and *food-drive*).

Each verb was presented in one of two contexts. In each context, the verb examined was introduced as a noun (to distinguish its meaning from ordinary uses of the corresponding irregular verb), and then later used as a verb. The contexts in which the verbs were presented were identical apart from a single semantic contextualizing sentence (shown in italics in Table 1)

that was varied across the contexts to manipulate the degree of semantic similarity between the verb and the ordinary irregular verb from which it was derived.

Table 1 - Example Context (The denominal verb is highlighted).

To promote business, the pesticide shop always stands a man in a giant fly costume at the entrance of their shop, to greet customers. This is especially fun for children. Whenever a child enters the shop, the greeter performs "the fly". The greeter tells the children jokes and gives out prizes. In the shop, the term to describe how the greeter greets children in this way is "to fly them". One hot day in June, sweating in his fly costume, I saw the greeter fly 40 children in a single afternoon. The look of tiredness on his face was really something.

Alternate context sentence

The child sits between the wings on the greeter's back, and they buzz up and down the aisles, ducking and swooping.

The two contextualizing sentences are italicized in table 1. The first context described an action that had some semantic similarity to *flying* simpliciter. The second context was semantically dissimilar to *flying* simpliciter. In order to obtain independent confirmation of the predicted semantic similarities, three naive raters were presented with the contexts on cards in randomized order and asked to order the contexts in each set according to how much the actions described in them matched the action they normally associated with the appropriate irregular verb (*fly*, *drink*, *sink*, and *drive*). The raters concurred with the ordering assigned to the contexts in the experiment, and inter-rater agreement was 100%.

Procedure

Participants told they were taking part in a memory study. Passages were presented on-screen and participants were instructed to memorize them. After memorizing a particular passage, participants were asked to indicate whether five sentences relating to the context passage were "True or False" by pressing the appropriate button on a computer keyboard as quickly as they could whilst concentrating on accuracy. The correct answer to three of these questions was "False" (e.g., in relation to the example in Table 1 participants were asked to state whether "The greeter was dressed as a pig" was true or false). The other two questions checked that participants remembered the noun use of the verb in question (e.g. "The greeter performs 'the Fly'") and also that they had remembered the semantic reinforcement sentences in the context. The correct

answers to these questions were always "True." The presentation order of these five preliminary questions was randomized.

A final, sixth sentence presented to participants was also true, but it presented a fact stated in the initial context in a passive voice as an active past tense. This tense took either a regular or irregular form, e.g. in relation to "One hot day in June, sweating in his fly costume, I saw the greeter fly 40 children..." the fact was presented in an actively voiced manner, e.g.: "The greeter flew 40 children." or "The greeter flied 40 children."

The delay in milliseconds between the presentation of this sentence on-screen, and the onset of participants' responses was recorded.

Each participant was presented with one training item, followed by one context from each of the four sets of stimuli. Each participant completed one from each of the four conditions of the experiment (e.g. a context describing an action that was semantically similar to that implied by an existing irregular verb, with the verb inflected regularly in the target sentence (e.g. *fly* – *flied*), similar context / irregularly inflected verb, dissimilar context / irregularly inflected verb and dissimilar context / regularly inflected verb).

The experimental task was embedded in a series of unrelated tasks that participants also completed.

Table 2 - Mean reading times in milliseconds for the target sentences in Experiment 1.

	Semantically similar irregular	Semantically to dissimilar irregular	to
drank	1490	2084	
drinked	2759	1642	
food-drove	1781	2166	
food-driven	2435	1577	
flew	2483	3051	
flied	2776	1686	
sank	1342	2890	
sunk	1873	1582	

Results

The mean reading time for each item is given in Table 2. Two unrelated t-tests showed that as predicted by single-route models (and in contrast to dual-route predictions) the target sentences containing the regular past tense forms of the verbs were processed faster in the dissimilar context (mean sentence reading time = 1622 ms) than in the similar contexts (2461 ms); $t(70)=3.282$, $p<0.001$. Irregular past-tense forms were processed more easily (1774 ms) when they had first been presented in an uninflected form in a context that was semantically similar to their ordinary usage as

opposed to a dissimilar context (2548 ms); $t(70)=2.178, p<0.02$.

Two-way repeated measures analyses of variance (ANOVAs) were conducted on the reaction time data, treating both subjects (F_1) and items (F_2) as random effects. There were no reliable main effects of either Meaning, $F_1(1,35)=0.23, p>0.87$; $F_2(1,3)=0.22, p>0.89$, or Grammaticality (Regular versus Irregular verb types) $F_1(1,35)=.235, p<.63$; $F_2(1,3)=.309, p>.6$. The lack of a Meaning main effect indicates that, collapsing over the paragraph contexts in which the verbs were embedded, meaning did not produce a processing bias for the verbs. The lack of a main effect of Grammaticality indicates an analogous absence of bias for regular or irregular verbs forms.

There was a significant Meaning \times Grammaticality interaction: $F_1(1,35)=12.911, p<0.001$; $F_2(1,3)=156.978, p<0.001$. As indicated by Figure 1, the interaction was due to Meaning effects at each level of Grammaticality (Regular versus Irregular verb types).

Figure 1. Overall reaction times in Experiment 1.

There were no significant increases in the error rate (participants answering "false" to statements that were assumed to be true) across all of the test sentences. For the true test sentences that were common to each context (the denominational and semantic reinforcement sentences) it was 10.4%. When the semantic context was consistent with the predicted verb tense the error

rate for the target sentences was 12.5% and the inconsistent error rate = 9.7%. The error rates for particular tenses of the target verbs were 12.5% for irregulars and 9.7% for regulars. Further ANOVAS were calculated considering only the "True" responses to the tests sentences containing the target verbs, which again showed no main effects of Meaning, $F_1(1,35)=0.138, p>0.71$; $F_2(1,3)=0.000$, or Grammaticality $F_1(1,3)=1.131, p=0.3$; $F_2(1,3)=.519, p>.5$, but did show a significant Meaning \times Grammaticality interaction: $F_1(1,35)=10.635, p<0.005$; $F_2(1,3)=99.047, p<0.005$.

Discussion

Consistent with findings in ratings and elicitation tasks (Ramscar, in press), it appears from the results of this experiment that semantics affect the on-line comprehension of both regular and irregular past tense forms. Strikingly, the on-line processing of regular forms was significantly affected by semantics: if participants had to read "the greeter *fled* 40 children" in a context where to "do the fly" involved something like ordinary *flying* while dressed in an insect costume, it took longer to process than when "doing the fly" involved telling jokes and giving out prizes clad in the self-same fly outfit. This was despite the fact that the participants behavioral responses were identical in either instance: participants agreed in each case that it was true that "the greeter *fled* 40 children."

These findings are difficult to reconcile with the claim that the processing of regularly inflected forms is entirely "independent of real-world meaning" (Pinker, 1991). Further, the interaction between meaning and past tense form (i.e. whether a verb takes a regular or irregular inflection) in this experiment is hardly suggestive of a model in which two independent mechanisms are separately responsible for regular and irregular past tense processing, with one element – the regular – encapsulated and insensitive to the semantic factors that affect the other. Rather, it appears that both regular and irregular past tense comprehension relies upon a common, semantically – and phonologically – sensitive process.

General Discussion

For more than two decades the question of how inflectional morphology is processed has served as a battleground for conflicting theories of language, knowledge representation, and cognitive processing. On one side of the debate have been similarity-based or single-route approaches that propose that all past tenses are formed simply through phonological and semantic analogies to existing past tenses stored in memory. On the other side of the debate are rule-based or dual-route approaches which agree that phonological analogy is important for producing irregular past tenses, but which also argue that regular inflection can *only* be explained in terms of symbolic processing.

Ramscar (in press) has shown that the one in principle objection *against* single-route accounts of

inflection – that homophone verbs based on nouns are processed on the basis of their grammatical origins, and not according to their phonological properties – is empirically unjustified: grammatical origin does not predict the past tense form of verbs, whereas phonology and semantics does. This paper has taken one of the strong claims for the dual-route theory of inflection – that the regular past tense rule is an informationally encapsulated module (see Fodor, 1983) – and subjected it to empirical scrutiny. Pinker and colleagues (e.g. Pinker, 1991, 1999, 2001; Clahsen, 1999; Kim, Pinker, Prince & Prasada, 1991) have claimed that the processing of regular inflection is driven by an innate mechanism that is unaffected by phonology, frequency or semantics. Results from the two experiments reported here fail to support this claim. Rather, they have shown conclusively that semantics does affect regular past tense comprehension, both of existing forms that may have been stored in memory, and of novel forms that needed to be interpreted on-line.

As Pinker (1999) observes, it is more than reasonable to assume that the same basic process (or processes) are responsible for both past tense production and comprehension. Ramscar (in press) showed that regular past tense production – in elicited inflection tasks – was apparently affected by semantics. The results reported here complement these findings, and extend them in that they provide an objective on-line measure of the effects of semantics on inflection (most previous studies of inflection have relied on subjective judgments and ratings to measure inflection processes, e.g. Ramscar, in press; Ullman, 1999; Prasada & Pinker, 1993; Kim et al, 1991). The results of this experiment show that – objectively – participants found regular past tense forms easier to process when the semantic contexts they were related to supported a regular form even though their subjective responses to regular forms were the same as when they were not supported by semantic context (i.e. in both cases, they considered the information carried by the regular forms to be true).

The pattern of results reported here is easily compatible with a model of inflection that assumes that past tense forms are computed (in both comprehension and production) by a process of comparison to previously stored forms, taking into consideration factors such as phonological and semantic similarity and frequency.

That these results are not compatible with the idea that regular inflection is processed independently from the contents of memory, and that it is entirely unaffected by factors such as phonological and semantic similarity and frequency (see Pinker, 1991, 1999, 2001) does not, of course, mean that the dual-route model is necessarily wrong (these results no more disprove the idea that *some* regular inflection is carried out in this context-independent manner than does the existence of still more white swans disprove the idea of orange swans). However, insofar as Ramscar (in press)

has shown that one of the key reasons for positing a context-independent regular past tense rule (to deal with denominal verbs, which were supposedly regularized irrespective of their phonological and semantic properties) is unjustified, and insofar as the experiments reported here suggest that semantic and phonological comparisons in associative memory (a component that even the dual-route model accepts is necessary to model inflection) affect even the comprehension of novel inflected forms, it does seem worth considering what role it is that a context-independent rule is supposed play in a scientific account of inflection. There is an increasing body of evidence suggesting that a context-independent rule does not add anything substantive to our understanding of inflection (see e.g. Hahn & Nakisa, 2000; Ramscar, in press), and further, it appears that *any* inflection can be processed in associative memory (see Ramscar, in press and the experiments reported here) a component that even dual-route models accept is necessary to modeling inflectional morphology (see Pinker, 1991, 1999, 2001).

This evidence (and on a more mundane level, Occam's razor) militates against the inclusion of an explicit, context-independent rule in any psychological theory of inflection. At present, it appears that a similarity-based, single-route account of inflection – in which forms are processed by matching and analogous generalization according to factors such as phonological and semantic similarity and frequency – provides a more economical explanation of, and a better fit to, the available data. To return to Rumelhart and McClelland's (1986) claim, it appears that children (and adults) may well *not* need to learn the rules of the English past tense in any explicit sense. As far as the English past tense system goes, it appears that the parser does *not* make "basically the same distinctions as the grammar" (Clahsen, 1999, p. 995). While the "grammar" of English may distinguish between irregular and regular past tense forms, these results suggest that the corresponding psychological processes that govern parsing do not make these explicit distinctions at all.

Abstract

One central function of categories is to allow people to infer the presence of features that cannot be directly observed. Although the effect of observing past category members on such inferences has been considered, the effect of theoretical or causal knowledge about the category has not. We compared the effects of causal laws on feature prediction with the effects of the inter-feature correlations that are produced by those laws, and with the effect of exemplar typicality or similarity. Feature predictions were strongly influenced by causal knowledge. However, they were also influenced by similarity, in violation of normative behavior as defined by a Bayesian network view of causal reasoning. Finally, feature predictions were not influenced by the presence of correlations among features in observed category members, indicating that causal relations versus correlations lead to different inferences regarding the presence of unobserved features.

When an object has been classified as an instance of a concept, knowledge associated with that concept can be brought to bear in reasoning about the features that the object is likely to possess. But what is the nature of that knowledge, and how is it used to make inferences or predictions about unobserved features? Recent research has demonstrated that tasks such as category learning, categorization, and category-based induction are often influenced by the theoretical knowledge that one possesses. This knowledge often takes the form of causal relations between features of a category, and theories have been proposed to account for the effects of such knowledge (Rehder, 1999, 2001; Waldmann, Holyoak, & Fratianne, 1995). In this article we assess the effect of causal relations on feature inferences, and in the first of the following sections we present a formal model of causal knowledge and its predictions regarding feature inferences.

Of course, another form of knowledge that may guide feature inference is empirical information derived from the first-hand observation of category members. Prior research suggests two likely effects of such empirical knowledge on feature prediction. First, feature predictions will often be influenced by the overall similarity to the category of the exemplar with the unobserved feature. In the second section we discuss this predicted effect of similarity and show how it can run directly counter to the predictions of our formal model of causal knowledge. Second, the presence of correlations among category features may also allow one to infer

the presence of a feature given knowledge about the presence of one or more other features. We discuss the effects of observed inter-feature correlations in the third section, and compare them to the effects produced by direct knowledge of causal relations—relations that were responsible for generating the feature correlations in the first place.

Feature Inference via Causal Reasoning

It is clear that causal knowledge has predictive value. For example, given knowledge of the causes of fire, one can predict, with some certainty, that a flame will appear when a match is struck, oxygen is present, and so on. Likewise, given the causal relations that hold among features of an object, the presence of an unobserved feature can be inferred by reasoning about the causes of that feature and whether those causes are present in the object at hand.

In this article we provide direct evidence of causal reasoning in feature inference, and we test a well specified theory about how this sort of reasoning might be done. This theory involves Bayesian networks—graphs in which variables are represented as nodes, and causal relations between the variables as directed links between the nodes. Figure 1 shows a simple Bayesian network in which three effect variables are dependent on a single cause variable.

Rules by which inferences can be drawn from Bayesian networks have been well developed in artificial intelligence. One important rule is the *causal Markov condition*, which states that a variable X is independent of all variables that are not themselves descendants of X given knowledge about the state of X 's (immediate) parents (Pearl, 1988). In Figure 1, for example, the state of F_2 is independent of F_3 and F_4 given knowledge about F_1 .

It has been proposed that Bayesian networks are good psychological models of causal knowledge—and, in particular, of the causal knowledge associated with object concepts

Figure 1. A common-cause causal schema.

(Rehder, 1999, 2001; Waldmann et al., 1995). On this *causal-model theory* of concepts, the model shown in Figure 1 can be used to represent a concept with four features, where feature F_1 causes features F_2 , F_3 , and F_4 . Representing causal knowledge of category features in this way has been shown to account well for classification (Rehder, 1999, 2001), but it is an open question whether the rules of inference associated with Bayesian networks—and, in particular, the causal Markov condition—accurately describe people's inferences about unobserved features.

In this article we tackle this question by explicitly manipulating the causal knowledge about a category that a participant has and measuring the effects of that knowledge on subsequent feature predictions. Participants in a *Causal Schema* condition were told that the features of a novel category were related as in the common-cause model of Figure 1, and were then asked to make inferences about exemplars in which one of the four features was unobservable. We determined whether participants' responses were consistent with the causal Markov condition.

Feature Inference via Category Similarity

Another factor likely to influence the prediction of an unobserved feature is the similarity of the exemplar to previously observed category members (or to the category's prototype). In this case, inference is based on simple feature overlap. If an exemplar is similar to (i.e., shares many features with) many category members, and if many category members possess the unobserved feature, then the exemplar probably has the feature too. For example, if a new bird has many features typical of birds (small, sings, eats worms, etc.) it probably also flies, because it is similar to many birds and most birds fly. In contrast, a new bird with many atypical features (e.g., an ostrich) is similar to fewer birds, and so the inference to flight is less certain.

Previous research has shown that similarity plays a key role in a variety of feature inference tasks. For example, Sloman's (1993) feature-based model of the inductive projection of features across categories assumes that a feature is projected from, say, robins to falcons by computing the extent to which they have other features in common (cf. Rips, 1975). Sloman also found a phenomenon called "inclusion similarity" in which participants projected a property from an inclusive category to a subordinate (e.g., from bird to robin) more strongly when the subordinate was more typical (e.g., robin) than when it was less so (e.g., penguin). Direct evidence of the role of similarity in feature prediction (rather than projecting new features across categories) was provided by Yamauchi and Markman (2000), who taught participants artificial categories and found that exemplars that were closer to the category prototype (i.e., that possessed more features in common with training exemplars) supported stronger inferences of unobserved features.

The influence of similarity on feature inference presents a particularly stringent test of the causal Markov condition, because honoring the causal Markov condition can require one to ignore similarity. For a category with a common-cause causal schema (Figure 1), the causal Markov condition states that information about the presence or absence of F_2

and F_3 is irrelevant to inferring F_4 given knowledge of F_1 . In contrast, an influence of similarity predicts that inferences to F_4 will be stronger when F_2 and F_3 are present, because the presence of F_2 and F_3 means that the exemplar is more similar to the category prototype.

In the following experiment participants in the *Control* condition were told that each feature had a 75% base rate (as were Causal Schema participants), but were not instructed on any causal relationships. Results from the Control condition will indicate an effect of similarity if feature inferences increase as a function of the exemplar's similarity to this central tendency (i.e., as a function of the number of features). Results from the Causal Schema condition will indicate whether participants are able to override this effect of similarity, as required by the causal Markov condition.

Feature Inference via Feature Correlations

The final influence on feature prediction performance we consider is the presence of within-category feature correlations. For example, many people know that birds that are small tend to sing whereas large birds do not, and on the basis of this correlation might infer the presence of a small bird upon hearing song, or the absence of singing from a large bird—and do so despite having no knowledge of the causal mechanisms that link size and singing.

Prior research confirms the intuition that the observation of within-category feature correlations can influence feature predictions, at least when participants observe category exemplars during standard classification-with-feedback training. Some studies (Thomas, 1998; Yamauchi & Markman 1998) have attributed this result to participants' similarity-matching to the training exemplars with a multiplicative similarity rule that preserves sensitivity to feature correlations. Others (Anderson & Fincham, 1996) attribute it to participants' inducing a direct representation of those inter-feature correlations (also see Wattenmaker, 1993).

A final goal of the current article was to compare the effect of causal laws on feature inference with the effect of observing the inter-feature correlations produced by those laws. In the following experiment, participants in the *Exemplars* condition were told that each feature manifested a 75% base rate, as were participants in the Causal Schema and Control conditions. But then, rather than being instructed on causal relationships, they instead observed a sample of exemplars that manifested the inter-feature correlational structure that is implied by a common-cause causal schema (i.e., exemplars with strong correlations between feature F_1 and features F_2 , F_3 , and F_4). Because it reflects causal laws, feature prediction performance based on this correlational structure should ideally be qualitatively similar to performance based on knowledge of the laws alone. In particular, inferences regarding the presence of an unobserved effect feature should be stronger when F_1 is present as compared to one of the other features.

Method

Materials

Six novel categories were used: two biological kinds (Kehoe Ants, Lake Victoria Shrimp), two nonliving natural kinds

(Myastars, Meteoric Sodium Carbonate), and two artifacts (Romanian Rogos [cars], Neptune Personal Computers). Each category had four binary features. For example, for the Lake Victoria Shrimp category the four binary features were "a high quantity of ACh neurotransmitter," "long-lasting flight response," "accelerated sleep cycle," and "high body weight." Each feature was described as occurring in 75% of category members. Participants in the Causal Schema condition were also taught about three causal relationships between F_1 and F_2 , F_3 , and F_4 . Each description of a causal relationship specified the cause feature, the effect feature, and a brief description of causal mechanism linking them. For example, the $F_1 \rightarrow F_2$ causal relationship for Lake Victoria Shrimp was "A high quantity of ACh neurotransmitter causes a long-lasting flight response. The duration of the electrical signal to the muscles is longer because of the excess amount of neurotransmitter."

Participants

Fifty-four undergraduates or other members of the Northwestern University community received course credit or pay for participating in this experiment.

Design

Participants were randomly assigned in equal numbers to one of the six categories, and to either the Causal Schema, the Exemplars, or the Control condition.

Procedure

All phases of the experiment were conducted by computer. Participants first studied several screens of information about the assigned category at their own pace. All participants read a cover story and a description of the features and their 75% base rates. Participants in the Causal Schema condition also received a description of three causal relationships, and a diagram depicting those relationships similar to Figure 1. When ready, all participants took a multiple-choice test of this knowledge. Participants could request help, which led the computer to re-present the information about the category. Participants were required to retake the test until they made 0 errors and 0 requests for help.

Participants in the Exemplars condition then observed 48 examples of the category. Although the studies reviewed above found feature prediction performance to be sensitive to feature correlations when training exemplars were observed in a classification-with-feedback task, Wattenmaker (1991) found that participants were more sensitive to feature correlations on a transfer categorization test when they were asked simply to "look over, examine, and learn about" exemplars. Thus, category exemplars were presented sequentially at a pace determined by the participants. They observed 26, 3, 3, 3, 1, 1, 1, 2, 2, 2, and 4 instances of exemplars 1111, 1110, 1101, 1011, 0110, 0101, 0011, 0100, 0010, 0001 and 0000, respectively, where "1" denotes the presence of a feature, "0" represents its absence, and features are given in dimension order (F_1 , F_2 , F_3 , F_4). These exemplars manifest the 75% feature base rates that participants were instructed on, and also the correlational structure that is implied by a common-cause causal schema. Specifically, the strength of

the correlations between F_1 and F_2 , F_3 , and F_4 was $r = .62$, and the correlations among F_2 , F_3 , and F_4 conditional on F_1 were approximately 0. The features of each exemplar were listed in order (1–4) on the computer screen. For example, participants assigned to the Lake Victoria Shrimp category were presented with three category members that possessed "high amounts of the ACh neurotransmitter," "a normal flight response," "accelerated sleep cycle," and "high body weight." The order of the 48 exemplars was randomized for each participant.

Participants in all conditions then performed two tasks (counterbalanced for order): a feature prediction task and a categorization task. During the feature prediction task, participants were presented with 32 exemplars, each with an unobserved value on one of the four dimensions, and were asked to rate the likelihood that the feature was present on a 100-point scale. For each unobserved dimension the other three dimensions took on the eight possible combinations of values, yielding a total of 32 feature prediction problems. The features of each exemplar were listed in dimension order (1–4), with the unknown dimension designated with "???" For example, participants assigned to the Lake Victoria Shrimp category were presented with the feature list "normal amounts of the ACh neurotransmitter," "a fast flight response," "???", and "high body weight" and asked to rate on a 100-point scale whether this exemplar had an "accelerated sleep cycle." The order of the 32 feature prediction problems was randomized for each participant.

During the categorization task, participants rated the category membership of exemplars on a 100-point scale. There were 32 exemplars, consisting of all possible 16 examples that could be formed from four binary features, each presented twice. The order of the 32 test exemplars was randomized for each participant.

Results

Feature Prediction Results

Because results for those feature prediction problems in which the unobserved feature dimension was the first dimension were not directly relevant to the theoretical issues raised in this article, we report results only for those problems in which the unobserved feature was on the second, third, or fourth dimension. Figure 2 presents feature prediction ratings as a function of the total number of features in the exemplar, whether the common-cause feature (F_1) is present or absent in that exemplar, and experimental condition (Causal Schema, Control, or Exemplar). Note that the number of features in F_1 -Present problems ranges from 1 to 3 whereas the number in F_1 -Absent problems ranges from 0 to 2 because of the presence of F_1 itself in the F_1 -Present problems.

In the Causal Schema condition (Figure 2a) feature prediction ratings were strongly influenced by the presence or absence of the common cause F_1 as compared to one of the other features. For example, problems with one feature received a much higher rating when that feature was F_1 (e.g., the feature prediction problem 1x00) than when it was one of the other features (e.g., 0x10), 70.6 versus 24.5. Similarly, problems with two features received a higher rating when one of those features was F_1 (e.g., 1x10) than when

Figure 2. Feature prediction results in the (a) Causal Schema, (b) Control, and (c) Exemplars conditions

neither was F_1 (e.g., 0x11), 80.9 versus 32.8. That is, Causal Schema participants were much more likely to reason from the presence (or absence) of the common-cause feature F_1 to infer the presence (or absence) of an effect than when they were reasoning from one of the effect features.

According to the causal Markov condition, inferring the presence of an effect in a common-cause schema should not only depend on the common cause feature F_1 , it should also *not* depend on any of the effect features. In fact, Figure 2a indicates that feature prediction ratings increased as the number of effect features increased. In the F_1 -absent condition, feature prediction ratings were 6.7, 24.5, and 32.9 for exemplars possessing 0, 1, and 2 effect features, respectively. This occurred despite the fact that, according to the causal Markov condition, the absence of common cause F_1 makes the presence or absence of other effects irrelevant for predicting an effect feature. Likewise, in the F_1 -present condition, ratings were 70.5, 80.9, and 92.8 for exemplars possessing 1, 2, and 3 features, respectively. That is, although Causal Schema participants' feature prediction ratings were strongly influenced by the causal knowledge that was provided, they also exhibited a substantial similarity effect in which more features led to stronger inferences, in violation of the causal Markov condition.

In comparison with the Causal Schema condition, results from the Control condition (Figure 2b) indicate that the effect of the presence or absence of F_1 on feature prediction ratings was not greater than the effects of the other features. This result was expected, because in the Control condition there was nothing about F_1 to make it especially predictive of an unobserved feature. However, as in the Causal Schema condition, feature prediction ratings exhibited an effect of similarity; ratings increased as a function of the number of features present in the exemplar. Ratings were 37.4, 53.6, 63.1, and 73.7 for exemplars that possessed 0, 1, 2, or 3 features, respectively. Note that this effect of similarity obtained despite the fact that the Control participants observed no members of the category, but rather just read a verbal statement of the 75% feature base rates.

These conclusions were supported by statistical analysis. Each participant's ratings were predicted from a regression

equation in which the two predictors were the number of features present and a contrast code representing the presence or absence of F_1 . As expected, in the Causal Schema condition the regression weight associated with the presence or absence of F_1 was both significantly greater than zero, $t(35) = 6.95$, $p < .0001$, and significantly different than the corresponding weight in the Control condition, $t(34) = 5.65$, $p < .0001$. Moreover, in both the Causal Schema condition and the Control condition the regression weight associated with the number of features was significantly different from zero, $t(35) = 4.89$, $p < .0001$, and $t(35) = 2.79$, $p < .01$, respectively. This sensitivity to number of features did not differ between the Causal Schema and Control conditions, $t < 1$.

Finally, Figure 2c presents the results from the Exemplars condition. The figure indicates that, in contrast to the Causal Schema condition, the presence of F_1 resulted in only a small increase in feature prediction ratings as compared to one of the other features. For example, whereas in the Causal Schema condition problems received a feature prediction rating that was about 50 points higher when F_1 was present in the exemplar (Figure 2a), in the Exemplars condition that difference was only 10.9 points (52.9 vs. 42.0) for one-feature exemplars and 12.4 points (69.3 vs. 56.9) for two-feature exemplars. This result obtained despite the presence of strong correlations between F_1 and the other features in the training exemplars that might have been expected to lead subjects to treat F_1 as especially predictive. In fact, the regression weight associated with the presence or absence of F_1 in the Exemplars condition was not significantly different from the Control condition, $t(34) = 1.17$, $p > .20$.

As in the Causal Schema and Control conditions, feature prediction ratings in the Exemplars condition were sensitive to the total number of features possessed by the exemplar. Ratings were 24.2, 44.2, 65.1, and 94.0 for exemplars that possessed 0, 1, 2, or 3 features, respectively. The regression weight associated with the number of features was greater than the corresponding regression weight in the Control condition, $t(34) = 2.12$, $p < .05$. In other words, the observation of exemplars that manifested the 75% feature base rates led participants to be more sensitive to similarity as compared to the Control condition, in which participants

were simply told about the 75% feature base rates.

Individual differences. On a finer level of analysis, there is some clustering in the data. Informally, the response patterns given by participants in the Causal Schema condition fell into a few different classes, and the most frequent was in fact the one that respects the causal Markov condition (uniformly low ratings when F_1 is absent, uniformly high ratings when F_1 is present). A look at the Causal Schema subjects' regression weights (see Figure 3) revealed a group of 8 "causal Markov" subjects who weighted the presence or absence of F_1 heavily and the number of features lightly, 3 "similarity" subjects who weighted the number of features heavily and F_1 lightly, and 7 "compromisers" who assigned moderate weights to both predictors. In contrast, examination of the Exemplars condition revealed 2 causal Markov subjects, 11 similarity subjects, and 2 compromisers (3 subjects weighted neither factor). That is, whereas the modal response in the Exemplars condition was similarity based, the modal response in the Causal Schema condition was consistent with the causal Markov condition.

Figure 3. Regressions weights for individual subjects.

Categorization Results

One purpose of the categorization task was to ask to what extent feature inference was mediated by the goodness of category membership of the exemplar with the unobserved feature. We summarize the main findings. First, in the Causal Schema condition categorization ratings were influenced by the two factors that influenced feature predictions: They increased as the number of features in the exemplar increased (i.e., as the exemplar's similarity increased), and they increased even more when the causally central F_1 was present (i.e., the pattern shown for feature predictions in Figure 2a). However, unlike the prediction ratings, the categorization ratings were also sensitive to whether the causal relation between F_1 and each of the other observed features was confirmed or violated (i.e., whether F_1 and each of the effect features were jointly present/absent or not), a finding replicating past results (Rehder & Hastie, 2001). In other words, whereas categorization ratings showed a sensitivity to all three of the relations that constitute a common-cause schema, for purposes of predicting unobserved features participants apparently attended to only the relation in which

the unobserved feature dimension was involved. The result was a dissociation between feature prediction and categorization ratings in the Causal Schema condition.

Second, in the Exemplars condition category membership ratings, like the feature prediction ratings, were sensitive to similarity but insensitive to the presence or absence of F_1 as compared to other features (cf. Figure 2c). However, unlike the feature prediction ratings the categorization ratings were also sensitive to whether the correlations between F_1 and each of the other observed features were broken or preserved.

Importantly, this latter result speaks to the possibility that Exemplars participants' insensitivity to the presence or absence of F_1 during the feature prediction task arose merely as consequence of their failing to learn and encode the correlations involving F_1 . In fact, results from the categorization task indicate that participants encoded these correlations but did not make use of them in feature inference. This represents a dissociation between feature inference and categorization, just as in the Causal Schema condition.

Finally, in the Control condition both category membership and feature prediction ratings were monotonic functions of the number of features present, that is, the featural similarity of the exemplar to the category prototype.

General Discussion

The first question asked in the current article was whether causal knowledge about a category influences predictions regarding the presence or absence of unobserved features. In fact, we found that causal knowledge had a strong effect on those inferences. Reasoners were much more likely to predict the presence of an unobserved feature when its cause was present than when that cause was absent. In this respect, their reasoning was similar to the normative method of inference defined by Bayesian networks.

These results contribute to a collection of findings demonstrating the importance of theoretical or explanatory knowledge in variety of feature inference tasks. For example, Lassaline (1996) found that the projection of a new property from one category to another was stronger when causal knowledge supportive of that property was provided (also see Sloman, 1994). Rehder & Ross (2001) found that the learning of a category via a feature prediction task proceeded more rapidly when features were related on the basis of prior knowledge. However, so far as we know, the current study is the first to address the specific role of causal knowledge in inferring the presence of unobserved features in a category with known causal structure.

Although causal knowledge had a profound effect on feature predictions, we also found that normative Bayesian reasoning is not the whole story. Even when reasoners had causal knowledge, their feature inferences showed a persistent effect of overall similarity to the category, such that an exemplar with a greater number of category-associated features was deemed more likely to have an unobserved feature. This was true even though the features that contributed to similarity were conditionally independent of the unobserved feature in question. In this respect, the effect of causal knowledge on feature predictions violated the causal Markov condition associated with Bayesian networks.

The influence of similarity on feature predictions also ob-

tained in the Control condition. This effect held even though participants did not observe category members (in contrast to previous studies demonstrating similarity effects, e.g., Yamauchi & Markman, 2000), but rather were provided only with a verbal statement of the 75% feature base rates. Under these conditions one might have expected that Control participants would be especially likely to assume independence among features (i.e., base each prediction only on the base rate of the feature in question and not on the presence/absence of other features). The current results indicate people's tendency to reason on the basis of central tendency or prototype information holds even when that information is provided in summary form (and without any mention of correlations between features) rather than experientially.

On the one hand, these findings are reminiscent of other studies that have attempted—mostly in vain—to induce participants to ignore the effects of similarity (e.g., Allen & Brooks, 1991). However, our analysis of individual differences revealed considerable variation among participants in the relative importance of causal knowledge and similarity. In fact, 8 of 18 participants in the Causal Schema condition ignored similarity (that is, they honored the causal Markov condition) when predicting unobserved features, indicating that similarity-based responding is not obligatory. The question of under what conditions feature inferences are dominated by theoretical and causal knowledge versus featural similarity is one that merits further investigation.

Another question we asked was whether causal knowledge has a different effect than inter-feature correlational knowledge. Rather than being given an explicit causal model, participants in the Exemplars condition observed exemplars that manifested the correlations implied by that model. In fact, though, the vast majority (14 of 18) of Exemplars participants failed to use those correlations in making feature inferences, and their inferences were qualitatively like those of Control subjects, who had neither causal nor empirical knowledge. Instead, the effect of the empirical observations was merely to make feature predictions even more sensitive to the degree to which an exemplar was similar to the category's prototype.

This finding contrasts with previous studies in which feature prediction was found to be sensitive to inter-feature correlations, at least when those correlations were observed during a classification-with-feedback task (Anderson & Fincham, 1996; Thomas, 1998; Yamauchi & Markman, 1998). We used a different learning task, in which participants were asked merely to observe category members, but we know that the inter-feature correlations were learned and encoded during this task because they were reflected in participants' categorization ratings. That the same participants failed to use these correlations in feature inference represents a dissociation between categorization and feature inference.

More generally, in both the Causal Schema and the Exemplars conditions, we found that categorization ratings and feature inferences were sensitive to different kinds of information: Categorization but not feature prediction was sensitive to the overall causal or correlational structure instantiated in an exemplar. This implies that feature inference is not merely mediated by goodness of category membership. Instead, participants in both of these conditions used the

category knowledge they possessed in different ways depending on the task at hand. That is, whereas Yamauchi and Markman (1998) have suggested that category representations will differ depending on whether they are acquired via categorization or feature prediction, the current results suggest that categorization and feature prediction tasks can also draw on different aspects of a single representation.

Abstract

Routines may help groups to effectively reduce coordination requirements when solving interdependent tasks. However, routine problem solving always involves the risk of a negative transfer, which appears if a routine is applied to novel problems even though it is inappropriate. In this experiment, negative transfer was produced by first teaching individuals a procedure for solving the Tower of Hanoi problem. Next, participants were asked to solve several transfer tasks either individually or in pairs. However, the routine could not be applied directly to the transfer tasks but led to a long detour. As expected, the individuals surpassed the dyads, who insisted more strongly on their routine. This result fits with studies that corroborate the claim that groups are prone to a "principle of inertia" when solving problems or making decisions.

Introduction

A *routine* may be defined as a well practiced problem solving procedure, which has been applied repeatedly and, therefore, does not need much planning but may be executed rather automatically (for an overview on various definitions, see Betsch, Haberstroh, & Hoehle, in press). Typically, in the problem-solving domain, routines consist of several single action steps that have to be executed in a particular order. Even though the single steps may require some planning, the sequence of the steps itself is usually highly internalized. From this automation follows that procedures or schemata that have become a routine may easily be transferred to novel tasks. However, routines are not only transferred to structurally equivalent tasks (positive transfer), but are sometimes also applied to tasks that share only surface features with the learning task. Accordingly, there is ample evidence showing that the successful use of a scheme enhances the likelihood of a *negative transfer effect*, i.e., worse performance compared to a condition in which the scheme has not been repeatedly applied before (cf. VanLehn, 1996).

In the present study, we sought to extend the literature on learning transfer to group problem solving. In particular, the study aimed at testing whether negative transfer effects are more pronounced in dyads

than in individuals. On the one hand, it may be more likely that a dyad recognizes a change in task demands. On the other hand, adapting a routine in a group usually requires coordination processes, which may cause process losses (cf. Gersick & Hackman, 1990). Moreover, there are several studies showing that groups often tend to accentuate preferences or decisions that are held by a majority (cf. Hinsz, Tindale, & Vollrath, 1997). In general, if individuals are predisposed to process information in a biased way, then, groups usually tend to enhance this bias. However, if groups use strategies more reliably and consistently than individuals, then, transfer effects should also be enhanced in groups, irrespective of whether this transfer is positive or negative.

In this study, the hypothesis that negative transfer is more pronounced in groups than in individuals was tested by asking participants to solve Tower of Hanoi problems either individually or in pairs. There are several procedures that guarantee an optimal solution of the Tower of Hanoi problem (cf. Simon, 1975). In order to produce transfer effects, participants were first taught either the goal-recursion (R) or the move-pattern procedure (M). These two procedures differ in two aspects, which make them suitable for studying transfer effects within the Tower of Hanoi problem:

- (1) Only the R-procedure but not the M-procedure may be directly applied to a transfer task in which the start peg is the middle peg.
- (2) The two procedures lead to different patterns of move latencies. Hence, differences in move latencies may be used as an indicator of the respective procedure applied and to what extent a problem solver insisted on his/her routine.

Whereas the first study tested for process losses in pairs, the second study compared homogeneous with heterogeneous pairs and additionally considered individual learning.

The Tower of Hanoi Problem

The Tower of Hanoi problem consists of three pegs and a fixed number of disks of different sizes (Simon, 1975). The original task is to move all the disks from the left to the right peg under the following constraints

(cf. Figure 1): (a) only one disk may be moved at a time, (b) only the disk that is on the top of the pyramid may be moved, and (c) a larger disk may never be placed on top of a smaller disk. A problem with n disks requires a minimum of $2^n - 1$ moves.

Figure 1: The Tower of Hanoi problem.

The goal-recursion procedure The *goal-recursion procedure* (R) consists in forming sub-goals. Each problem with $n > 1$ disks can be decomposed into three sub-problems: Into (1) a problem consisting of $n-1$ disks, (2) the move of the largest disk from the start peg onto the goal peg, and (3) into a second problem consisting of $n-1$ disks.

For example, the four-disk problem in Figure 1 can be decomposed into two three-disk problems and the move of a single disk: (1) First of all, the three-disk pyramid (consisting of the disks 2 to 4) has to be moved from the start peg onto the middle peg; (2) in the next step, the largest disk (number 1) can be moved onto the goal peg; and (3) finally, the three-disk pyramid has to be moved again, this time from the middle peg onto the goal peg. The three-disk problem is itself a Tower of Hanoi problem with one disk less than the original problem. Hence, the three-disk problem can be decomposed into two two-disk problems and the move of a single disk. Thus, the recursion procedure is based on a chunking strategy by dividing a problem into sub-problems until only one disk remains and there is no longer any problem.

The move-pattern procedure The *move-pattern procedure* (M), on the other hand, is based on a stimulus-driven instead of a goal-driven heuristic, without formulating any sub-goals. According to this procedure, one has to learn a particular pattern of moves, whereby attention has to be paid to the *position* of a disk and to its *parity*: *Odd*-numbered disks should always be moved from the left to the right, from the middle to the left, and from the right to the middle. *Even*-numbered disks are moved the other way round, from the left to the middle, from the middle to the right, and from the right to the left. Additionally, the same disk should never be moved twice in one go. The latter

constraint guarantees that it is always clear which disk is to be moved next. For example, according to these rules, disk 4 in Figure 1 should be moved onto the middle peg because it is an even-numbered disk. Next, disk number 3 should be moved onto the right peg, because the same disk should never be moved twice in one go and 3 is an odd number.

Original vs. transfer tasks It is worth noticing that both procedures lead to the same pattern of moves and to an optimal solution, provided all rules are strictly adhered to. This functional equivalence holds for any number of disks. However, if the start peg is the *middle* peg instead of the left peg, only the recursion-procedure is optimal. The move-pattern procedure may be applied to such a *transfer task* as well, but it requires twice as many moves as the optimal goal-recursion procedure: If a transfer task is solved by applying the move-pattern procedure, the entire tower moves first onto the left peg and then onto the right peg.¹

Differences in move-latencies Even though both procedures lead to the same pattern of moves with original tasks, they differ in the amount of planning and, therefore, result in different patterns of *move latencies* (cf. Reimer, 2001a). If the M-procedure is applied, the cognitive effort is almost the same for all moves (despite the fact that the decision as to which disk should be moved next may vary among different game situations). Thus, a player who applies the M-procedure is expected to move disks relatively regularly. According to the R-procedure though, at the very beginning as well as in situations, in which a new sub-tower has to be solved, extensive planning is required. Whereas these “first moves” should last long, subsequent moves (i.e., all other moves) should be carried out fast in order to execute the planned recursion smoothly without extensive interruptions. Hence, ideally, an application of the R-procedure results in high latencies in the first moves and short latencies when subsequent moves are performed.

In general, the extent to which a player spends more time on first moves than on subsequent moves may be quantified by the following strategy index (S):

$$S = FM / SM,$$

with FM = mean time for first moves and SM = mean time for subsequent moves. Because the M- and R-procedure differ in the extent of chunking and planning, participants who were taught the R-procedure were expected to score higher on the strategy index than participants who had been taught the M-procedure (S_R

¹ In order to meet this criterion, the original move-pattern procedure, which was described by Simon (1975), was slightly changed by linking the move patterns to the left, middle, and right peg instead of the start and the goal peg.

> S_M). Additionally, the strategy index may also serve as a measure of the extent to which participants in the M-condition change their strategy towards a chunking-strategy when solving transfer tasks.

Study 1

The first study aimed at (1) testing for differences in performance between pairs and individuals, and, in particular, to test whether the M-pairs suffer from any process losses when solving transfer tasks (*process-loss hypothesis*); (2) testing the claim that the M-pairs insist more strongly on their procedure than the M-individuals, which should result in a lower strategy index for the M-pairs than the M-individuals (*persistence hypothesis*); and (3) testing to what extent the potential process losses are mediated by the strategy index (*mediation hypothesis*).

Method

Sample and design The design consisted of three factors: Firstly, participants were individually taught either the R- or the M-procedure (factor *procedure*). Secondly, participants solved problems either individually (I) or in pairs (P) (factor *group*). Finally, type of task was varied as a within-subjects factor. Each individual and each pair had to solve two original and two transfer tasks, one four- and one five-disk problem each.² The 90 students who participated in the study were randomly distributed among experimental conditions (15 pairs in the conditions R-P and M-P and 15 individuals in the conditions R-I and M-I).

Procedure Each participant was first individually explained the R- or the M-procedure. Additionally, each person completed a computerized training run with 30 tasks that always required only a single move. In the *R-condition*, their task was to solve sub-problems. For this purpose, one or more disks were already marked on the computer screen. The respondent's task consisted in moving the respective sub-problem in the correct direction. In the *M-condition*, respondents were also confronted with different game situations. Here, the task consisted in executing the next move according to the M-procedure. In both conditions, immediate feedback was provided by the computer on whether the single move was correct or wrong.

In the testing phase, participants were asked to solve two original and two transfer tasks in as few moves as possible. In the pair condition, they moved in turns

without communicating with each other. The opportunity to correct or to undo moves by moving a disk twice in one go was explicitly mentioned in the instructions. If a person tried to place a larger disk on top of a smaller one, an error message appeared on the screen.

Results

Number of moves Table 1 shows the mean number of moves that were required by the individuals and pairs. An ANOVA with the factors, *procedure* (R vs. M), *group* (I vs. P), and *task* (original vs. transfer tasks), revealed an interaction of *task x procedure*, which was due to negative transfer in the M-condition ($F(1,56)_{\text{task} \times \text{procedure}} = 115.51$; $p < .01$; $F(1,56)_{\text{procedure}} = 94.32$; $p < .01$; $F(1,56)_{\text{group}} = 0.13$; ns; $F(1,56)_{\text{task}} = 121.43$; $p < .01$). In the R-condition, the original as well as the transfer tasks were solved almost perfectly ($M_{\text{original task}} = 24.15$; $M_{\text{transfer task}} = 24.38$; $t(29) = -.50$; ns).

Table 1: Mean Number of Moves.

	R		M	
	I	P	I	P
Original tasks	24.83	23.47	25.87	23.50
Transfer tasks	25.20	23.57	39.97	46.77

However, participants who had been taught the move-pattern procedure required many more moves to solve the transfer tasks than the original tasks ($M_{\text{original task}} = 24.68$; $M_{\text{transfer task}} = 43.37$; $t(29) = -10.2$; $p < .01$). Moreover, as can be seen in Table 1, this negative transfer was enhanced in the group of the M-pairs. Accordingly, the two-way interaction was further qualified by a significant three-way interaction of *task x procedure x pair*, $F(1,56) = 7.55$; $p < .05$. Obviously, the M-pairs suffered much more from their routine than the M-individuals when solving transfer tasks ($t(28) = 2.17$; $p < .05$).

Move latencies Are these process losses caused by a higher persistency of the M-pairs? First, as expected, participants in the R-condition had much higher strategy indices than participants in the M-condition throughout (cf. Table 2).³ This holds true for original tasks ($t(58) = 8.3$; $p < .01$) as well as for transfer tasks ($t(58) = 4.28$; $p < .01$).

Additional ANOVAs, which were conducted separately for the M- and the R-condition, confirmed the persistency hypothesis:

² For the following analyses, measures were aggregated across the four- and five-disk problems throughout. Problems with four disks are solvable in 15 moves and problems with five disks require 31 moves. Thus, the minimum number of moves is 23, irrespective of the task conditions, i.e., regardless of whether original or transfer tasks are solved.

³ The distribution of latencies was positively skewed. For this reason, each latency per move was transformed first by taking the logarithm. All reported analyses are based on these transformed latencies.

Table 2: Mean Strategy Index.

	R		M	
	I	P	I	P
Original tasks	1.16	1.08	1.04	1.02
Transfer tasks	1.18	1.09	1.10	1.02

In both analyses, the main effect of *group* ($F_{R(1,28)} = 55.61$; $F_{M(1,28)} = 12.88$; $ps < .01$) was significant, indicating higher strategy indices for the individuals than for the pairs. These main effects may be explained by the time that is required by the pairs when taking turns. Secondly, there was also a significant main effect of *type of task* in both conditions: Overall, participants in the R- ($F_{R(1,28)} = 6.27$; $p < .05$) as well as in the M-condition ($F_{M(1,28)} = 6.94$; $p < .05$) showed higher strategy indices when solving transfer tasks compared with original tasks. However, only in the M-condition the two main effects were qualified by a significant interaction ($F_{M(1,28)} = 5.16$; $p < .05$; $F_{R(1,28)} = 0.70$; ns). As can be seen in Table 2, the M-individuals had a much higher strategy index in the transfer tasks than in the original tasks ($t(14) = 2.70$; $p < .05$), whereas the M-pairs did not change the way in which they structured the problem solving process ($t(14) = 0.44$; ns).

Predicting performance by the strategy index The observed persistency may also serve as an explanation for the differences in performance. In order to show that the observed process losses are due to the extent to which the M-individuals and M-pairs changed towards a chunking strategy, an ANCOVA on the number of moves was run using the strategy index as a covariate. As can be seen in Figure 2, which refers exclusively to the M-condition and to the transfer tasks, the observed process losses disappear if differences in the strategy index are controlled.

Discussion

Participants who had been taught the goal-recursion procedure did not have any serious problems solving the transfer tasks (positive transfer). Within the move-pattern condition, however, a negative transfer effect appeared. Further, the M-pairs performed worse on the transfer tasks than the M-individuals, which confirms the process-loss hypothesis. However, these process losses do not seem to be due to mere mutual distraction in the pairs, that is, it is unlikely that participants distracted each other in general when joining a dyad. If this were the case similar process losses should have been observed in the other pair conditions, too. Rather, the results confirm the persistency hypothesis: Obviously, the M-pairs did not only need many more moves to solve the transfer tasks but also insisted more strongly

on using their strategy than the M-individuals, who reacted much more flexibly and tried to adopt a chunking strategy.⁴

In general, participants in the R-condition spent more time on the first than on subsequent moves, whereas participants in the move-pattern condition made their moves much more regularly. Thus, in the original tasks, the participants in the R- and M-condition did not differ in their performance, but could easily be identified on the basis of their strategy index. Moreover, differences in performance disappeared when differences in the strategy index were controlled (mediation hypothesis).

Thus, the first study confirms the assumption that negative transfer effects will be enhanced by dyads who were taught the same inappropriate routine and, therefore, share a common knowledge. However, it is reasonable to assume that it is this unanimity in particular that puts the pairs at a disadvantage. According to this interpretation, persistency was fostered by the fact that both members had learned the same inappropriate procedure. However, if this is true, then, *heterogeneous pairs* should perform much better, in particular if one member has access to an appropriate procedure. On the other hand, if participants persist in their procedure irrespective of what the other person does, such a mixed pair should not perform better than a uniform M-pair.

Study 2

This issue was addressed in the second study, in which each person belonged to a pair condition. In order to test for the heterogeneity hypothesis, a mixed pair-condition was introduced, which consisted of one M- and one R-participant (condition MR). Additionally, immediately after the learning phase and at the very end of the experiment, participants were also asked to solve several tasks individually in order to test for differences in individual learning.

Method

Sample, design, and procedure The sample consisted of 112 senior high school students who were randomly assigned to one of the three pair-conditions, MM, MR, or, RR, under the restriction of approximately equal numbers within the mixed (26) and uniform pairs (15 pairs each). First, as in experiment 1, each participant was individually taught either the M- or the R-procedure. During the testing phase, each pair had again to solve four tasks, two original and two transfer tasks, of which one problem consisted of four and one of five disks.

⁴ As further evidence for the persistency hypothesis, a classification of single moves revealed that the M-pairs carried out relatively more moves that are in accordance with the move-pattern procedure than the M-individuals when solving transfer tasks (cf. Reimer, 2001a).

Figure 2: Path diagram: Study 1.

Additionally, participants had to individually solve two original problems with four and five disks prior to the group condition and two respective transfer problems immediately after the group condition.

Results

Single person condition I Table 3 shows the mean number of moves that were required by the individuals solving original problems immediately after the learning phase. This table is not based on the dyads but rather on the single persons as unit of analysis. For example, the condition *R / Uniform* refers to those participants who had been taught the goal-recursion procedure and who joined a person in the group condition who had access to the same procedure.

Table 3: Mean Number of Moves in the Individuals.

	R		M	
	Uniform	Mixed	Uniform	Mixed
Original tasks	29.33	26.68	28.08	26.72
Transfer tasks	28.35	28.22	52.32	49.54

An ANOVA with the factors *procedure* (R vs. M) and *group* (uniform vs. mixed) confirmed that there were no significant differences between the three experimental pair conditions on the individual level prior to the group condition (all $F_s < 2$; ns). Even though it is again impossible to identify the procedures on the basis of the number of moves, the two conditions M and R may be identified on the basis of their strategy index.

As is shown in Table 4, participants who were taught the R-procedure had higher scores on the strategy index than participants in the M-condition. Accordingly, a 2x2 ANOVA revealed a strong main effect of *procedure* ($F(1,108) = 121.9$; $p < .01$; F_s for the main effect of *group* and the interaction were less than 1).

Group condition A 2x3 ANOVA on the number of moves showed two main effects (cf. Table 5):

(1) Overall, more moves were made to solve the transfer tasks than to solve the original tasks (main effect of *type of task*: $F(1,53) = 100.26$; $p < .01$).

Table 4: Mean Strategy Index in the Individuals.

	R		M	
	Uniform	Mixed	Uniform	Mixed
Original tasks	1.17	1.17	1.05	1.04
Transfer tasks	1.16	1.17	1.08	1.05

(2) The highest number of moves was required in the uniform move-pattern condition (MM). The mixed pairs (MR) took the middle position and the RR-pairs performed best (main effect of *group*: $F(2,53) = 38.08$; $p < .01$).

(3) However, as expected, there was again a significant interaction of *type of task x group*, $F(2,53) = 37.08$; $p < .01$. As can be seen in Table 5, the differences between the pairs were almost exclusively due to the transfer tasks.

Table 5: Mean Number of Moves in the Pairs.

	RR	MR	MM
Original tasks	23.47	23.77	23.50
Transfer tasks	23.57	31.71	46.77

Overall, the observed pattern in performance may be described as follows: Whereas the original problems were solved almost optimally in each condition, there were huge differences in performance between the pairs on the transfer tasks. These difficulties were most pronounced in the MM-condition and to a much lesser extent in the MR-condition. In the RR-condition, participants had no problems with the transfer tasks at all. Interestingly, the mixed pairs, who differed significantly from the MM- as well as from the RR-pairs, performed better than the pooled uniform pairs ($M_{MR} = 31.71$; $M_{MM/RR} = 35.17$; $p < .05$).

As expected, the pairs also differed consistently in the extent to which they applied a recursion strategy (cf. Table 6). A 2x3 ANOVA on the strategy index revealed a main effect of *group*, $F(2,53) = 29.35$; $p < .01$ (the F_s for the main effect of *type of task* and the interaction were < 1.3 ; ns). Within the original as well as the transfer tasks, the three pair conditions may be rank ordered on the basis of their strategy index ($S_{RR} > S_{MR} > S_{MM}$).

Table 6: Mean Strategy Index in the Pairs.

	RR	MR	MM
Original tasks	1.09	1.05	1.02
Transfer tasks	1.10	1.05	1.03

Moreover, in analogy to experiment 1, the differences in performance were, at least partially, mediated by the strategy index. If the strategy index was included as a covariate, differences in performance were reduced ($F(2,53) = 38.08$ vs. $F(2,52) = 20.0$; effect of the strategy index as a covariate: $F(1,52) = 57.5$; all $ps < .01$).

Single person condition II Table 3 and 4 (see above) also show the mean number of moves and the strategy indices in the final test of the individuals. In this test (1) the R-individuals achieved better results than the M-individuals (main effect of *procedure*: $F(1,108) = 54.03$; $p < .01$). (2) There were no significant differences in performance between the M-individuals who had joined an M- or an R-partner in the group condition (the F s for the effects of *group* and of *procedure* \times *group* were < 1 ; ns). (3) Analogous results were also observed for the strategy index (main effect of *procedure*: $F(1,108) = 92.33$; $p < .01$; neither the main effect of *group* nor the interaction were significant).

Discussion

As in the first study, the original tasks were solved almost perfectly by all pairs, even by the mixed MR-pairs. Here, the two distinct procedures converged to a common problem solution (cf. Reimer, 2001b). The result, i.e., that these pairs performed much better on the transfer tasks than the uniform M-pairs, suggests that group heterogeneity improved performance. Further analyses of the contributions of the M- and R-individuals within the mixed groups revealed that the M-participants performed significantly better when solving problems in mixed pairs than in uniform pairs. The M-participants who belonged to a mixed pair made a much higher relative number of correct moves than the M-participants who belonged to a uniform pair. This pattern was reversed for the R-participants who performed worse in the mixed pairs than in the uniform pairs. Even though this seems to support the heterogeneity hypothesis, an interesting question for further research would be whether the advantage of the M-participants who joined a mixed group had also appeared if both players had been taught *distinct inappropriate* procedures. Astonishingly, the advantage of the M-participants who belonged to the MR-pairs disappeared in the final test. However, when interpreting the results on individual learning, one should keep in mind that the pairs were not allowed to talk to each other and, therefore, had no opportunity to explain and even exchange their ideas.

Whether communication enhances or reduces the observed process losses may be another interesting issue for future research likewise the question whether the findings can be generalized to groups that consist of more than two members. In general, we can expect that the larger the groups the stronger the transfer effects supposing a group consists of homogeneous group members that share the same routine. As far as the communication issue is concerned, there is at least some evidence that communication enhances performance in pairs who have not been taught a routine but who have to develop a common strategy (cf. Reimer, 2001a).

Overall, these studies confirm the claim that groups who have routinized a problem solving procedure persist more strongly in their routine than individuals. Groups tend to behave like "ocean steamers": They often need much time and effort to work out an efficient problem solving procedure. However, once having reached a solution they are likely to persist in their routine and stick to their course irrespective of changes in the environment. The most obvious *advantage* for a group in following "the principle of inertia" consists in saving time and energy, because routines need not be actively managed and, subsequently, reduce coordination requirements (cf. Gersick & Hackman, 1990). Moreover, in situations in which the "ocean steamer" is on the right course and a routine is appropriate, groups may be expected to *surpass* individuals (cf. Hinsz et al., 1997) by better compensating for individual errors and by fostering positive transfer.

Abstract

Although several studies propose computational models of the process by which children acquire the syntax of their native language, most focus on a single algorithm applied in a single domain. Typically, the focus is *learnability* – under what conditions an algorithm can or cannot acquire the grammar of the target (native) language. Here, we present a comparative study of 12 algorithmic heuristics that are run in a domain that consists of 16 abstract languages each generated by a different grammar specified in Chomsky's principles and parameters framework. The heuristics consist of both those used in previously established models and new variations that we introduce. In contrast to a learnability study, our focus is *feasibility* – how much time and/or effort is required to achieve the target grammar. We find that the best heuristics make use of structural information obtained by parsing input sentences during the course of learning, that the performance of statistically-based heuristics are next in line, and finally, that heuristics that make use of hill-climbing search and a simple *can-parse/can't-parse* outcome from the parsing mechanism perform least well.

Background

Principles and Parameters

Chomsky (1981 and elsewhere) has proposed that all natural languages share the same innate universal principles (Universal Grammar - UG) and differ only with respect to the settings of a finite number of (binary) parameters. For example, all languages have a subject of some sort, but whether a language's grammar dictates that the subject must be overt is determined by the setting of the *null subject* parameter. The null subject parameter is set *off* in English and *on* in Spanish. The syntactic component of a grammar in the *principles and parameters* (P&P) framework is simply a collection of parameter values – one value per parameter. The set of human grammars is the set of all possible combinations of parameter values.

Language Acquisition The P&P framework was motivated to a large degree by psycholinguistic data demonstrating the extreme efficiency of human language acquisition. Children acquire the grammar of their native language at an early age – generally accepted to be in the neighborhood of five years old. In the P&P framework, if the linguistic theory delineates over a billion possible grammars by positing 30 parameters ($2^{30}=1,073,741,824$), a learner need only determine the correct 30 values that comprise the target grammar (henceforth, G_{target}).

Given the generally accepted presupposition that a compelling theory of human language should show grammars to be easily

acquirable, and since, at least on face value, parameters seem transparently learnable, it is not surprising that parameters have been incorporated into many current generative syntactic theories. However, the exact process of parameter setting has been studied only recently (cf. Bertolo, 2001 and references therein; Briscoe, 2000; Clark, 1992; Fodor, 1998a; Gibson & Wexler, 1994; Yang, 2000; among others), and although it has proved linguistically fruitful to construct parametric analyses, it turns out to be surprisingly difficult to construct a workable model of parametric syntax acquisition.

Parametric Ambiguity and the Need for Heuristics A sentence is parametrically ambiguous if it is licensed by two or more distinct combinations of parameter values. Parametric ambiguity is rampant in natural language. For example, a sequence of the form Subject-Verb-Object (SVO) is parametrically ambiguous between underlying SVO order as in English, and *verb second* (V2) order as in German.¹ Although SVO sentences can be parsed by either grammar, the derivations will be different due to the different parameter settings. By contrast, a VOS sentence is not parametrically ambiguous with respect to the V2 parameter. It can be licensed only by the -V2 value (since the second token is not a verb or auxiliary).

Ambiguity is a natural enemy of efficient language acquisition. The key problem is that, due to ambiguity, there does not exist a one-to-one correspondence between the linear left-to-right word order of an input sequence and the correct parameter values for the target grammar (as described above for an SVO sentence with respect to + or -V2). So, even if the learner hypothesizes parameter values which license the *single*, current input sentence, those values may ultimately be incorrect for G_{target} . In the face of parametric ambiguity, efficient search heuristics must be employed to guide the learner towards the target grammar as sentences are progressively consumed by the learner. The remainder of the paper presents a comparative study of 12 search heuristics that are incorporated into current parameter-setting models of language acquisition.

Overview

A Measure of Feasibility

As a simple example of a learning heuristic and of our simulation approach, consider a domain of 4 parameters and a memoryless

¹ See Appendix for the linguistic details of how we implement the V2 parameter.

learner² which blindly guesses how all 4 parameters should be set upon encountering an input sentence. Since there are 4 parameters, there are 16 possible combinations of parameter settings ($2^4=16$), i.e., 16 different grammars. Assuming that each of the 16 grammars is equally likely to be guessed, the learner will consume, on average, 16 sentences before achieving G_{arg} . This is one measure of a model's efficiency or *feasibility*.

However, when modeling natural language acquisition, since practically all human learners attain the target grammar, the average number of expected inputs is a less informative statistic than the expected number of inputs required for, say, 99% of all simulation trials to succeed. For our blind-guess learner, this number is 72.³ We will use this 99 percentile feasibility measure (99% score) for most discussion that follows, but also include the average number of inputs for completeness.

Error-Driven Learning

Although an outside oracle could ascertain when the blind-guess learner has acquired the target grammar, the learner itself has no "built-in" mechanism for identifying that it has achieved the target. Even if the correct grammar is hypothesized, the learner will most likely abandon it on the next sentence (with a probability of 15/16) and hypothesize a different (incorrect) grammar.

A standard way to build target identification into an algorithm is to dictate that the learner be *error-driven*.⁴ Assuming that all inputs are grammatically correct instances of sentences that make up the target language, one could provide the learner with the ability to produce a *can-parse/can't-parse* outcome⁵ given the current input sentence, the current hypothesized grammar (G_{curr}), and the rule: *Don't change G_{curr} unless there is parse failure*. With this error-driven constraint, there is no need for an outside oracle to stop the learner from relinquishing the target grammar once it is attained. Since all sentences are generated (by definition) by G_{arg} , parse success is guaranteed once $G_{\text{arg}} = G_{\text{curr}}$, and thus the learner will not be motivated to shift from its current hypothesis.

An *Error-Driven Blind-Guess (EDBG)* learner is our first heuristic of interest. It is easy to show that the average and 99% scores increase exponentially in the number of parameters. Clearly, human learners do not employ any strategy that performs as poorly as this.

Table 1: EDBG, # of sentences consumed

	99%	Average
EDBG	86	15.09

² By "memoryless" we mean that the learner processes inputs one at a time without keeping a history of encountered inputs or past learning events.

³ The average and 99 percentile figures (16 and 72) in this section are easily derived from the fact that input consumption follows a hypergeometric distribution. See Chung (1979) for an overview.

⁴ Error-driven grammar learning was first introduced by Gold (1967) and has become a standard in learnability research.

⁵ We intend for a "can-parse/can't-parse outcome" to be equivalent to the result from a language membership test. If the current input sentence is one of the set of sentences generated by G_{curr} , *can-parse* is engendered; if not, *can't-parse*.

The Simulations

In all experiments:

- The learners are memoryless.
- The language *input sample* presented to the learner consists of only grammatical sentences generated by G_{arg} .
- The heuristics are tested in a 4-parameter, 16-language domain (see Appendix for details).
- For each heuristic, 1,000 trials were run for each start/target grammar pair.⁶
- At any point during the acquisition process, each sentence of G_{arg} is equally likely to be presented to the learner.⁷

Subset Avoidance and Other Local Maxima Depending on the algorithm and the learning domain, it may be the case that a learner will never be motivated to change G_{curr} , and hence be unable to ultimately achieve the target. This is often referred to as a *local maximum*. For example, the EDBG learner will be trapped if G_{curr} generates a language that is a superset of G_{arg} . There is a wealth of remarkable learnability literature that addresses local maxima and their ramifications.⁸ However, since our study's focus is on feasibility (rather than on whether a domain is learnable) given a particular algorithm, we posit a built-in avoidance mechanism, such as the *subset principle* and/or *default values* that preclude local maxima; hence, we set aside trials where a local maximum ensues.

The Heuristics

The heuristics we present can be separated into two families based on the way they process input sentences: those that guide the learner towards the target by use of a *can-parse/can't-parse* outcome, and those that take advantage of information gleaned from the parse trees that are constructed by the parser. Gibson and Wexler's (1994) *Triggering Learning Algorithm (TLA)* and Yang's (2000) *Variational Model* make use of *can-parse/can't-parse* outcomes only. Fodor's (1998a) *Structural Triggers Learner (STL)* takes advantage of more extensive structural information obtained from sentence parsing.

TLA

The TLA incorporates two search heuristics: the *Single Value Constraint (SVC)* and *Greediness*. In the event that G_{curr} cannot parse the current input sentence s , the TLA attempts a second

⁶ For the STL models presented later in the paper, the start grammar is unspecified.

⁷ Not reported here are results from simulations run on several different distributions of input sentences, in particular, those where the shorter (presumably simpler) sentences occur more frequently. The relative performance of the heuristics is substantially the same; however, in all cases acquisition requires more inputs. These distributions and their relationship to the rate of ambiguity in the domain are currently being analyzed. Also, see Niyogi & Berwick (1996) for mathematical treatment of how the distribution of inputs affects TLA performance.

⁸ Discussion of the problem of subset relationships among languages starts with Gold's (1967) seminal paper and is discussed in Berwick (1985) and Wexler & Manzini (1987). Detailed accounts of the types of local maxima that the learner might encounter in a domain substantially similar to the one we employ are given in Frank & Kapur (1996), Gibson & Wexler (1994), and Niyogi & Berwick (1996).

parse with a randomly chosen new grammar, G_{new} , that differs from G_{cur} by exactly one parameter value (SVC). If G_{new} can parse s , G_{new} becomes the new G_{cur} ; otherwise G_{new} is rejected as a hypothesis (Greediness). Following Berwick and Niyogi (1996), we also ran simulations on two variants of the TLA – one with the Greediness heuristic but without the SVC (TLA minus SVC, *TLA-SVC*) and one with the SVC but without Greediness (TLA minus Greediness, *TLA-Greed*). The TLA has become a seminal model and has been extensively studied (cf. Bertolo, 2001 and references therein; Berwick & Niyogi, 1996; Frank & Kapur, 1996; Sakas, 2000; among others). We will not rehash these earlier discussions here. We include the TLA in our study to present comparisons against other models.⁹

Table 2: TLA variants, # of sentences consumed

	99%	Average
TLA-SVC	117	18.12
TLA-Greed	102	19.44
TLA	227	22.56

The Variational Learner

Like other models, Yang’s *Variational Learner* (VL)¹⁰ incorporates the notion of a current grammar hypothesis (G_{cur}) which is applied to the current input sentence. However, unlike the other learners, the VL maintains, for each parameter, a *weight* varying from 0 to 1. Roughly, the weight of a parameter can be construed as a measure of the past successes (or failures) of either a 0 or 1 value for that parameter during prior parses of input sentences. If the weight is closer to 0, then the 0 value has been more successful; if the weight is closer to 1, the 1 value has been more successful.¹¹ The VL uses the weights to guide the selection of the next hypothesis.

Since Yang’s emphasis was on learnability in the limit and not on feasibility, in order to compare performance against other learners, we make a minor adaptation by adding a stopping criterion (see Step 4 below). The algorithm proceeds as follows:

1. Initialize weights for all parameters to 0.5.
2. Choose a new G_{cur} randomly, but biasing the choice towards parameter values favored by the current weights.
3. If G_{cur} succeeds in parsing the current input, nudge the weights in the direction of the values that make up G_{cur} (*reward* G_{cur}). This has the effect of making those parameter values that make up G_{cur} more likely to be chosen in the future. Otherwise nudge the weights away from G_{cur} ’s parameter values (*punish* G_{cur}).

⁹ In particular, the data in Table 2 reinforce Berwick & Niyogi’s (1996) conclusion that in addition to creating local maxima, SVC and Greediness reduce learning speed.

¹⁰ We use the proper name and acronym for readability; they are not used by Yang.

¹¹ Of course, if the values from one or more parameters are strongly tied to values of another parameter(s), the weight does not represent a simple ratio or percentage of success. Still, Yang’s intention is that the weights are an informative measure of past performance.

4. If all the weights are within a target threshold of either 0 or 1 then learning ends. Else go to Step 2.¹²

We chose 0.01 as the threshold value for stopping the learning process. Given weights w_1, w_2, \dots, w_n where n represents the number of parameters, learning ends if all weights are in the range: $0.0 \leq w_i < 0.01$ or $0.99 < w_i \leq 1.0$ (i.e., every weight is very close to either a 0 value or a 1 value). Note that this criterion could be UG-endowed; that is, an oracle is not required to stop the algorithm.

In both Yang’s original VL and the version presented above, the amount that the weights are “nudged” during learning is controlled by the *learning rate* (γ).¹³ We ran simulations with $\gamma=.1$, $\gamma=.5$, and $\gamma=.75$.

Yang’s model is of particular interest because it is an explicit implementation of the idea to keep statistics on the effectiveness of parameter settings based on the success or failure of past learning events. The reward/punish scheme of the VL is arguably an extension of error-driven learning in that incorrect grammars are punished, but it is significantly different from the standard constraint in which G_{cur} cannot change after a successful parse. The scheme works because the VL is statistical in nature; as parameter values vie for domination, the ones most successful in the past (and hence rewarded) are most likely to be chosen in the future and will eventually prevail.¹⁴

However, the statistical nature of the VL, together with the stopping criterion, may lead the learner to a local maximum. A parasitic input sample might lead to an abundance of evidence (i.e., successful parses) for incorrect parameter values early in the course of learning. If the learner encounters enough misleading evidence, it would cross the stopping threshold prematurely (on parameter values that are different from those that make up G_{cur}). This effect can be prevented by keeping the learning rate low, which gives the weights elbow room to fluctuate more gently until the evidence eventually supports the correct target. Unfortunately, the cost of keeping the learning rate low can be quite severe. In our 16-language domain, the VL requires well over 100,000 input sentences¹⁵ to achieve a 99% score with a learning rate of 0.1. When the learning rate was increased to 0.5, the expected number of inputs dropped to 242, and when the rate was increased to 0.75, the number dropped even further to 84, albeit with many more local maxima (learning failures).

To combat the extraordinarily high number of input sentences needed, we incorporated into Yang’s VL a variation of the

¹² This stopping criterion could lead the VL to converge on the wrong grammar. We consider these cases as local maxima, and as such, trials in which local maxima ensue are discarded. Also implemented was a different stopping criterion which requires that all the weights fall within a threshold of the values that make up G_{cur} . Clearly, this strategy could not be UG-endowed because it requires that the learner have advance knowledge of these values. It is also less efficient than the criterion above, though it does enforce convergence on the correct grammar.

¹³ The exact amount follows the Linear reward-penalty (L_RP) scheme (Bush & Mosteller, 1958). See Yang (2000) for details.

¹⁴ See Yang (2000) for a proof of convergence as the number of inputs approaches infinity.

¹⁵ We found that many trials required over 100,000 input sentences which was an arbitrary stopping point built into our simulation.

standard error-driven constraint.¹⁶ The *Error-Driven Variational Learner* (EDVL) proceeds as follows:

1. Initialize weights for all parameters to 0.5.
2. Randomly choose a new G_{curr} to start with.
3. If G_{curr} succeeds in parsing the current input, do nothing (no reward; no punish). Otherwise, randomly choose a new grammar (G_{new}) biased by the weights, re-parse with G_{new} , and apply Yang's original reward/punish scheme to adjust the weights.
4. Set G_{curr} to values **directly indicated by the weights** – that is, if $w_i > 0.5$, then the value of parameter i becomes 1, if $w_i < 0.5$, then the value of parameter i becomes 0, if $w_i = 0.5$, then either 0 or 1 is chosen at random.
5. Go to Step 3.

Note that no stopping criterion is needed, and that there are no local maxima because a move to another grammar is always possible before G_{curr} is attained. As is shown in the table below, the addition of the error-driven constraint greatly improves performance. Surprisingly, contra Yang's original model, performance **deteriorates** as the learning rate increases. We speculate that this is because a high learning rate encourages excessive exploration of different grammars, thus superseding the (positive) conservative nature of the error-driven constraint.

Table 3: VL & EDVL, # of sentences consumed

		99%	Average
VL	$\gamma = .1$	Over 100,000	Over 33,000
VL	$\gamma = .5$	242	46.35
VL	$\gamma = .75$	84	17.91
EDVL	$\gamma = .1$	44	8.39
EDVL	$\gamma = .5$	55	9.23
EDVL	$\gamma = .75$	75	12.16

STL

Fodor's *Structural Triggers Learner* (STL) makes greater use of the parser than the models discussed so far. A key feature of the model is that parameter values are not simply 0 or 1, but rather bits of tree structure or *treelets*. Thus, a grammar in the STL sense is a collection of treelets rather than a collection of 1's and 0's. The STL is error-driven. If G_{curr} cannot license s , new treelets will be utilized to achieve a successful parse.¹⁷ Treelets are applied in the same way as any "normal" grammar rule, so no unusual parsing activity is necessary. The STL hypothesizes grammars by adding parameter value treelets when they contribute to a successful parse.

The basic algorithm for all STL variants is:

1. If G_{curr} can parse the current input sentence, retain the treelets that make up G_{curr} .

2. Otherwise, parse the sentence making use of any or all parametric treelets made available by UG, and adopt those treelets that contribute to a successful parse.

The STL stands apart from other acquisition models in that it can detect when an input sentence is parametrically ambiguous. During a parse of s , if more than one treelet could be used by the parser (i.e., a *choice point* is encountered), then s is (possibly) parametrically ambiguous. The TLA and the VL do not have this capacity because they rely only on a can-parse/can't-parse outcome and do not have access to the on-line operations of the parser. Originally, the ability to detect ambiguity was employed in two variations of the STL: the *strong STL* (SSTL) and the *weak STL*.

The SSTL executes a full parallel parse of each input sentence and adopts only those treelets (parameter values) that are present in all the generated parse trees. Note that even if the surface word order of the input is ambiguous between several languages (i.e., the sentence belongs to more than one language), the SSTL can identify unambiguous parameter values (treelets) by looking at all of the tree structures that the parser constructs for the sentence. This makes the SSTL an extremely powerful model, and for this reason, it establishes an upper standard against which to compare other models. It is not, however, proposed as a psychologically realistic model. As with the Error-Driven Blind-Guess (EDBG) learner, it is clear that human learners do not exhibit an SSTL-like strategy. The consensus in sentence processing research is that adults are only capable of limited parallel parsing, if any (cf. Gibson, 1991). It does not seem plausible to suppose that children possess a more powerful mechanism than adults.

On the other hand, the weak STL executes a psychologically plausible left-to-right serial (deterministic) parse. One variant of the weak STL, the *waiting STL* (WSTL), deals with ambiguous inputs abiding by the heuristic: *Don't learn from sentences that contain a choice point*. These sentences are simply discarded for the purposes of learning. This is not to imply that children do not parse ambiguous sentences they hear, but only that they set no parameters if the current evidence is ambiguous.

Table 4: SSTL & WSTL, # of sentences consumed

	99%	Average
SSTL	14	3.35
WSTL	30	5.11

As with the TLA, these STL variants have been studied from a mathematical perspective (Bertolo et al., 1997; Sakas, 2000; Sakas & Fodor, 2001a). Although the simulation results indicate notably better performance than the other models examined thus far in this paper, previous mathematical analyses lend doubts to the ultimate success of the WSTL model. The WSTL requires some fully unambiguous sentences for any learning to take place. It is probably the case that fully unambiguous triggers are few and far between in the domain of human languages, and negative WSTL performance is exponentially tied to the rate of ambiguity in the domain; that is, in a more realistically ambiguous domain than the one we explored so far, the WSTL may consume and discard an extremely large number of sentences before attaining G_{curr} . This result has spurred a new class of weak STL variants

¹⁶ The resulting algorithm is similar to one originally proposed in Fodor (1998b).

¹⁷ In addition to the treelets, UG principles are also available for parsing, as they are in the other models discussed above. See Appendix for details that apply to the domain we use here.

which we informally call the *guessing STL* family (Sakas & Fodor, 2000).

The basic idea behind the guessing STL models is that there is some information available even in sentences that are ambiguous, and a strategy could exploit that information. We incorporate four different heuristics into the original STL paradigm:

- *Strong Oracle (SO)* – perform a parallel parse of the current input s and choose a hypothesis grammar that licenses s and is most similar (in terms of hamming distance) to G_{curr} .
- *Random Choice (RC)* – parse serially; when a choice point is encountered, randomly pick a parsing alternative and adopt the treelets that are present in the final tree structure.
- *Minimal Chain (MC)* – parse serially; when a choice point is encountered, pick the choice that obeys the *Minimal Chain Principle* (De Vincenzi, 1991), i.e., avoid positing movement transformations if possible.
- *Local Attachment/Late Closure (LAC)* – parse serially; when a choice point is encountered, pick the choice that attaches the new word to the current constituent (Frazier, 1978).

Although the MC and LAC heuristics are not stochastic, we regard them as “guessing” heuristics because, unlike the WSTL, a learner cannot be certain that the parametric treelets obtained from a parse guided by MC and LAC are correct for the target. These heuristics are based on well-established parsing preferences that adults employ, so it seems likely that children apply them also (Fodor, 1998b).

The SO heuristic was originally conceived by Fodor and Teller (2000) as an extension of the SVC. Their main point was the efficiency advantage that results from using the parser to find a successful parse of the current sentence, so that can’t-parse trials are eliminated. Given this capability, the question of how to choose among possible parses arises. The SO criterion presupposes full parallel parsing, which is unrealistic, but our approximation to it would result from letting the parser employ new treelets only where current ones do not suffice. Our data show that the conservatism of the SO heuristic pays off: it gives the strongest performance of any learner in our study, including the SSSL.

The RC, MC, and LAC heuristics show a significant improvement over the waiting strategy (WSTL). The difference between the three variants is slight.

Table 5: guessing STL family, # of sentences consumed

	99%	Average
SO	10	2.33
RC	26	3.43
MC	26	3.44
LAC	24	3.25

Conclusions

One can expect 86 sentences to be consumed by a population of (baseline) EDBG learners before 99% of the population acquires the target grammar in our small domain of 16 languages, and TLA variants require more input than that. The implemented heuristics in the two paradigms forego information, structural or statistical, in favor of a simple mechanism – the information

needed for language acquisition must somehow be available from the surface word strings that make up the languages of the domain. They will be successful only if either i) there are recognizable, unambiguous signals in the surface strings that trigger correct parameter values or ii) the distribution of cross-language ambiguity¹⁸ in the domain being studied is conducive to the heuristics being employed. There is faint evidence for both cases. For (i), in a domain without *null subject/topic*, the fact that a VOS sentence does not have a finite verb or auxiliary as the second token is indeed secure evidence for the -V2 parameter value. Although true for the -V2 value in this case, it is unclear how other plausible syntactic descriptions will offer the same advantage for the gamut of complicated linguistic phenomena (e.g., *null subject/topic*) with which human languages are inundated. As for (ii), previous work by the authors (Sakas, 2000) demonstrates that the TLA is a feasible learner in *strongly smooth* domains – domains in which there is a monotonic correlation between the similarity of grammars and the languages that are generated by them. Although still an open question, linguists have argued that natural languages are not strongly smooth.

The Error-Driven Variational Learner (EDVL) is a more promising model of language learning. On average, 44 sentences will allow 99% of the population to attain the target grammar. Its success can be attributed to the use of a strategy that maintains statistics of past performance without the unreasonable requirement that the learner memorize an entire input sample.

The most efficient heuristics, however, are those that make the most use of tree structure produced by the parsing mechanism: the psychologically plausible STL variants require almost half the number of inputs consumed by the EDVL.

Conjectures and Ongoing Research

The relative success of the EDVL is important for a reason not explicated earlier. Preliminary investigation points to the fact that, uniquely among the heuristics in our study, the EDVL performs more efficiently in ambiguous domains than in unambiguous ones at the outset of learning. This could turn out to be crucial as the guessing STL family might easily be foiled by larger, more syntactically complicated domains which generate sentences that contain a multitude of choice points – the result being that the parse tree computed for an input sentence, which guides parameter setting, reveals little about the target grammar. However, it has been shown that the STL performs extremely efficiently after just a few initial parameters have been set (Sakas, 2000). One can imagine a hybrid model of a guessing STL heuristic combined with a VL-like statistical heuristic where the statistical heuristic is used to bootstrap learning, and as performance deteriorates, the structural heuristic acquires more control of the acquisition process. This is being investigated in ongoing research.

The hard data that comprise our current study, however, reveal that the utilization of structural information outperforms the statistical heuristic overall.

¹⁸ For present purposes, cross-language ambiguity is defined as some measure based on the intersection of the sets of surface forms that make up the languages in the domain. See Fodor & Sakas (2001b) for other definitions and the effects of ambiguity on learning efficiency.

Appendix: Simulation Domain

The four parameters are: *Specifier Initial/Final*, *Complement Initial/Final*, *V2 Movement*, and *Null Subject-Topic*. We largely adopt the first three parameters from Gibson and Wexler (1994). The Specifier and Complement position parameters are non-transformational. It is assumed that the subject is base generated in Spec of IP, and that the verb moves to I in the final structure (if I is not filled with an auxiliary).

Input sequences are formed with tokens representing adverb, subject, verb, auxiliary, direct object, and indirect object. Following Gibson and Wexler, we assume that the learner can directly determine the role of a noun phrase. For example, the noun phrase *the big dog* is interpreted as a subject or one of the object types based on its role when uttered.

The following constraints on the domain are in place: all sentence types are degree-0 (i.e., no subordinate clauses); Spec of CP is to the left of C'; C always precedes IP; all adverbs are sentential (i.e., base generated in Spec of CP); and there is no transformational reordering of constituents (e.g., topicalization, wh-movement, scrambling, etc.) with the exception of the V2 movement described below.

The V2 Movement [+/-V2] parameter determines whether a finite verb moves to the second position in the root clause. That is, a "verb second" language [+V2] entails that the finite verb is transformationally fronted to C (from I) and that a topical element is moved into Spec of CP (if Spec of CP is not filled with an adverb). In a [-V2] language, the verb moves only up to I, and there is no movement of a topic into Spec of CP.

Extending Gibson and Wexler's domain, we add the Null Subject-Topic [+/-Null] parameter. This parameter represents either subject drop or topic drop depending on the value of the V2 parameter. In [-V2] languages, an overt subject is either optionally [+Null] (as in Spanish and Japanese) or obligatorily [-Null] (as in English). For [+V2] languages, the parameter works similarly, but instead of a subject, an overt topic may be optionally [+Null] or obligatorily [-Null].

Modeling Driver Distraction from Cognitive Tasks

Dario D. Salvucci (salvucci@mc.drexel.edu)

Department of Mathematics and Computer Science, Drexel University
3141 Chestnut St., Philadelphia, PA 19104

Abstract

Driver distraction has become a critical area of study both for research in investigating human multitasking abilities and for practical purposes in developing and constraining new in-vehicle devices. This work utilizes an integrated-model approach to predict driver distraction from a primarily cognitive secondary task. It integrates existing models for a sentence-span task and driving task and investigates two methods in which the resulting model can perform multitasking. Model predictions correspond well qualitatively to two of three measures of driver performance as collected in a recent empirical study. The paper includes a discussion of the potential for building multitasking models in the framework of a production-system cognitive architecture.

Introduction

Computational cognitive modeling continues to mature rapidly as an area for both theoretical advances in understanding cognition and practical advances in developing intelligent technology. Cognitive modeling has grown from addressing only simple cognition in basic psychological tasks to capturing integrated cognitive, perceptual, and motor processes in large-scale complex, dynamic tasks (e.g., Chong, 1998; Jones et al., 1999). This paper investigates the application of cognitive models to an extremely common yet complex task: driving. Driving involves the continual multitasking of a number of subprocesses that make use of the driver's cognition, perception, and motor movements. This rich spectrum of necessary skills makes driving an ideal task in which to investigate how humans execute complex tasks and how computational models can represent and predict the multitasking behavior in these tasks.

Driver Distraction and Cognitive Modeling

One particular aspect of driver multitasking that has received enormous attention from media and researchers alike is that of "driver distraction" -- namely, the effects of multitasking while performing some secondary task. Numerous studies have now found that performing primarily perceptual-motor tasks while driving (e.g., dialing a cellular phone) can impair driver performance (e.g., Alm & Nilsson, 1995; McKnight & McKnight, 1993). These studies generally conclude, perhaps not surprisingly, that pulling a driver's visual attention from the road and/or her hand(s) off the steering wheel degrades the driver's ability to maintain a central lane position, follow a lead car with a constant headway, or react to potential hazards. Such studies have

subsequently led to legislation at all government levels to restrict the use of potentially distracting secondary-task devices. While driver distraction is generally associated with effects on perceptual-motor processes, researchers have also reported that "cognitive distraction" arising from purely cognitive secondary tasks can adversely affect driver performance (e.g., Alm & Nilsson, 1995). These results are not fully conclusive and seem to depend highly on the secondary task as well as the driving situation; nevertheless, it is clear that even purely cognitive tasks can impact driver performance in certain situations.

To better understand driver behavior and the sources of driver distraction, researchers have attempted to develop integrated driver models that capture driver behavior in a computational manner (e.g., Aasman, 1995). These models provide insight into the sources of distraction by elucidating the exact processes by which a driver attends to the external environment, processes this information cognitively, and then reacts and manipulates the environment. In addition, the computational models may be used to generate predictions about the effects of distraction on driver performance; for instance, the ACT-R driver model (Salvucci, Boer, & Liu, 2001) has been integrated with various models of cell-phone dialing to predict the impact of dialing on lane-keeping performance (Salvucci, 2001; Salvucci & Macuga, 2001). However, this previous work has addressed only primarily perceptual-motor secondary tasks with little cognitive component (like cell-phone dialing); to date, no models have demonstrated the ability to represent and generate "cognitive distraction" from primarily cognitive tasks.

Modeling "Cognitive Distraction"

This paper describes the first attempt to predict cognitive distraction with a computational cognitive model. This work employs the same methodology as in previous work for perceptual-motor distraction, namely the "integrated model approach" based in a cognitive architecture (see Salvucci, 2001). Cognitive architectures are computational frameworks that incorporate built-in, well-tested parameters and constraints on human cognitive and perceptual-motor abilities. This work focuses on a particular architecture, ACT-R (Anderson & Lebiere, 1998), that represents factual knowledge as declarative chunks and procedural knowledge as condition-action "production rules". For our purposes, the ACT-R architecture has two important benefits: (1) it facilitates reuse and integration of multiple behavioral models, and (2) it provides built-in interfaces and default parameters that facilitate *a priori* predictions of real-world

metrics of human performance (e.g., reaction times, keystrokes, eye movements). The integrated model approach takes advantage of these benefits to incorporate a model of secondary-task behavior with the ACT-R driver model to predict the effects of executing the secondary task on the primary driving task.

The initial demonstrations of this approach (Salvucci, 2001; Salvucci & Macuga, 2001) examined a primarily perceptual-motor task, namely dialing a cellular phone using different modalities (e.g., manual button input versus speech input). The work showed that an integrated driving-dialing model predicted degraded steering performance for the modalities that required the driver to look at the cell phone (i.e., manual dialing), thus drawing visual attention away from the roadway. The work presented here generalizes the previous work in two important ways. First, although it utilizes the same methodology to predict driver distraction, it predicts distraction from a primarily cognitive task — namely, a sentence-span task that involves rehearsal and recall of a sequence of words. Second, unlike the previous work, it makes use of an existing model for the secondary task (with some necessary adaptation) as well as an existing model for the primary driving task, thus demonstrating the importance and benefits of model re-use.

This paper begins with a review of the driving and secondary tasks modeled here, namely those from the empirical work of Alm and Nilsson (1995) showing effects of the sentence-span task on driver car-following performance. It then provides an overview of the integrated model approach incorporating existing models of both the driving and secondary tasks, including two methods of performing explicit multitasking between the individual task models. Finally, it compares the model's predictions with Alm and Nilsson's empirical results and discusses the broader implications of the methodology to studying multitasking in the framework of a cognitive architecture.

The Sentence-Span and Driving Tasks

The task and empirical results that will be used to validate the model predictions are taken from Alm and Nilsson (1995). Their study aimed to show exactly those effects that we are attempting to model, namely effects of cognitive secondary tasks on driver performance. For the purposes of this paper, we would like to recreate this task for the integrated model as closely as possible to facilitate later comparison between model and empirical results.

Sentence-Span Task

Alm and Nilsson (1995) employed a sentence-span task that involves the processing of sentences and the recall of words in these sentences (see Daneman & Carpenter, 1980). The task comprises two stages. In the first stage, drivers listened to five sentences of the form "X does Y" — for instance, "The boy brushed his teeth" or "The train bought a newspaper." They would also report after each sentence whether the statement was generally sensible. In the second stage, drivers were asked to state the last word of each sentence in order. For instance, for the sentences "The boy brushed his teeth" and "The train bought a newspaper," the

driver would report "yes" and "no" after each sentence (respectively) and would then report the memorized list "teeth," "newspaper," etc. The sentence-span task itself involves two concurrent activities, namely judging of sentence sensibility and memorization (and rehearsal) of final words. When combined with driving, the task puts a substantial cognitive load on drivers as they attempt to integrate the tasks.

Driving Task

As a realistic scenario in which to test interaction with the sentence-span task, Alm and Nilsson (1995) used a car-following task where the lead vehicle would sometimes perform unsafe maneuvers and leave the driver in a "safety-critical" situation. During the normal stages of the task, the lead vehicle maintained a 75 m headway distance from the driver's vehicle. Occasionally, the lead car braked suddenly with a deceleration of 4 m/s^2 until its speed reached 50 km/hr (or until a maximum of 5 s of deceleration), then accelerated at 3 m/s^2 until its speed reached 90 km/hr. The original study also included non-safety-critical situations in which the lead vehicle would indicate a right turn and eventually turn off the road; their analysis does not examine these situations in detail and they are not discussed further.

The Alm and Nilsson study provided three metrics by which they measured driver performance: (1) reaction time to the braking event, measured as the time lapse between the start of the event and the driver's initial depression of the brake; (2) lateral deviation, measured as the root-mean-squared error of the driver's vehicle position to the center of the lane; and (3) headway distance, measured as the distance between the driver's vehicle and the lead vehicle. The results section will compare the model's predictions to the empirical results from human drivers for all three metrics.

Empirical Study

Alm and Nilsson's (1995) empirical study included a total of 40 participants in two experimental groups: a *task group* that occasionally performed the sentence-span task while driving, and a *control group* that did not perform the task. In both groups, each driver negotiated four safety-critical situations in which the lead vehicle would brake suddenly. The timing of the events was randomized to either near the start or near the end of the span task (in the task group) such that drivers could not predict when the events would occur.

The driving task was performed in a high-fidelity driving simulator to give participants as realistic an impression of real-world driving as possible. The simulator included a moving-base system (based on a Saab 9000 with manual transmission), wide-angle visual system, vibration generation, and temperature regulation. The driving environment comprised a simulated 80 km two-lane highway (one lane in each direction) with oncoming traffic in the opposite lane. The highway had a very low curvature so that steering down the roadway was relatively straightforward even at high speeds. The sentence-span task was performed through an Ericsson hands-free telephone mounted on the instrument panel to the right of the steering wheel. Drivers needed only press one key to activate

(answer) the phone at the start of the task, and given practice with the phone, drivers could easily activate the phone without looking. Sentences were presented by means of a tape recorder, and driver responses were recorded on a second tape recorder.

The results of the empirical study will be discussed in a later section to facilitate comparison with model predictions. It should be noted that the original study also included both younger and older drivers to demonstrate the interactions of cognitive distraction with age. This paper only addresses the data from the younger drivers (mean age 29); the existing driver model used in this paper has been validated with data from younger drivers, and thus we expect the model to better account for the younger-driver data from the original study.

The Integrated Task Models

To model and predict the interaction of the sentence-span and driving tasks, this work utilizes the "integrated model" methodology employed in previous work (see Salvucci, 2001): Given an existing model of driver behavior, we develop or acquire a model of behavior in the secondary task, integrate the two models to perform multitasking, and finally run the integrated model to generate behavioral data. One critical element of this integration is the potential for generating *a priori* predictions — that is, rather than fitting the model to data by manipulating parameters, we carry over defaults and parameter settings from existing models and immediately use them in the integrated model. In addition, we benefit from re-use of models that have been rigorously tested in other studies. These and related issues will be discussed further in later sections. This section describes the individual task models as well as the two versions of the final integrated model.

Sentence-Span Model

The model for the sentence-span task comes from Lovett, Daily, and Reder (2000), who developed an ACT-R (Anderson & Lebiere, 1998) process model as part of their investigation of individual differences in working memory. Although the original model does not literally perform the sentence-span task, it does perform a closely related task called the MODS task in which people read strings of letters while memorizing final digits for later recall. The original model provides three critical components that are re-used in the sentence-span model: (1) the positional representation used to encode memorized items, (2) production rules that perform rehearsal of memorized items, and (3) production rules that retrieve and report the items in sequence. Interested readers can refer to Lovett, Daily, and Reder (2000) for a more detailed description of these components.

Given this core model, the sentence-span model required two modifications: (1) the addition of production rules to encode a sentence and decide whether it is sensible, and (2) the incorporation of perceptual-motor productions to hear and speak words (rather than read and type characters as in the MODS task). Table 1 shows the production rules in the final sentence-span model and indicates those rules taken from the original MODS model. While there are a number

of new rules in this model, it should be noted that the first six deal with particulars of the sentence-span task involving hand movement and encoding of speech, and the final two non-MODS rules simply terminate the articulation and recall goals. The process of confirming whether or not the sentence is sensible is not modeled in any detail, but rather the model simply assumes that this process happens during the listening productions and signals a confirmation by firing the Confirm-sentence rule. In addition, the model assumes that each sentence component (subject, verb, object) requires one second of speech time.

Table 1: Sentence-span model production rules, with markings for whether they are original MODS-model rules and whether they pass control to driving in the Single-Step (SS) and Group-Step (GS) models.

Production Rule	MODS	Passes Control	
		SS	GS
Move-hand-to-phone		x	x
Press-button		x	x
Move-hand-to-wheel		x	x
Hear-sentence-subject		x	x
Hear-sentence-verb		x	x
Hear-sentence-object		x	x
Confirm-sentence		x	x
Create-memory	x	x	x
Rehearse-memory	x	x	
Done-articulate		x	x
Recall-span	x	x	
No-recall	x	x	
Say-item	x	x	
Next-item	x	x	x
Done-recall		x	x

Driver Model

The model of driver behavior is an ACT-R model that integrates control, monitoring, and decision making to navigate highway environments with traffic (Salvucci, Boer, & Liu, 2001). For control, the model employs a two-level model of steering that uses a "far point" on the road to guide predictive steering and a "near point" on the road to center the vehicle. For monitoring, the model encodes its surrounding environment using simulated eyes to maintain situation awareness. For decision making, the model checks the current situation and decides when to perform maneuvers such as lane changes. Thus, the driver model incorporates both lower-level perception and action for vehicle guidance and higher-level cognition for awareness and decision making. This driver model has been shown to account for a number of aspects of human highway driving, including nearing the inner curb during curve negotiation and switching gaze to the destination lane at the start of a lane change (see Salvucci, Boer, & Liu, 2001). Also, as mentioned earlier, the driver model has been employed to predict the effects of driver distraction from cell-phone dialing in different modalities (Salvucci, 2001a, 2001b; Salvucci & Macuga, 2001).

The complexities of the driver model make it infeasible to describe here in any level of detail. However, it is worthwhile to highlight two critical aspects of the model that are essential to the endeavor of predicting driver distraction. First, because of its implementation in the ACT-R architecture, the model is constrained to a serial line of cognitive processing. Thus, the cognitive integration of perception, action, and decision making is done in a serial loop: the model encodes relevant perceptual variables, processes these variables, then issues motor commands to manipulate the environment. When secondary tasks are added into this main loop, they naturally have some impact on the frequency with which the updating processes can occur, and thus can affect driver performance. Second, the driver model interacts with a simulated driving environment and generates a full behavioral protocol, as would a human driver navigating the same environment in a driving simulator. This faithfulness to predicting real-world data facilitates rigorous and straightforward comparison between model predictions and empirical results.

Integrated Model

In general, integration of multiple models in a production system such as ACT-R is rather straightforward: we can simply add the sentence-span memory structures to the driver model. However, two challenges arise that must be dealt with. First, the integrated model must decide how to multitask between the two component models. As in previous applications of this methodology, there does not yet exist a rigorous model of multitasking that we can employ, but we can use reasonable heuristics to guide us. Multitasking in the integrated model is performed explicitly (instead of preemptively) in that each model must pass control to the other, presumably at a fairly frequent interval. Because driving is the primary task, we are most concerned about when the secondary task model (i.e., the sentence-span model) will cede control back to driving. This paper explores two approaches for attacking this problem. The conservative approach would only allow the secondary task to fire a single production, then immediately cede control back to driving. A less conservative (though still fairly conservative) approach would allow small logical groupings of production firings to occur before passing control. These approaches were used to develop two versions of the model termed the Single-Step (SS) and Group-Step (GS) models, respectively. Table 1 indicates which productions pass control for each model. While every rule is marked for the SS model, the GS model allows certain rules to continue: the Rehearse-memory rule that rehearses memorized items in rapid succession, and the threesome of rules that combine to retrieve and report a memorized item. The choice of marked rules for the GS model is admittedly somewhat arbitrary, but at least in part guided by introspection as to how humans would perform this task. Further development on rigorous models of multitasking will help to formalize these choices in future work.

The second major challenge for model integration, not to mention model development on the whole, is the setting of parameter values. ACT-R, like similar architectures, has a number of "settable" parameters; however, all parameters have default recommended values that have withstood the test of time in modeling throughout the community. Nevertheless, the original MODS model posed an interesting problem in that it activated several learning mechanisms (e.g., learning of chunk base-level activations and production strengths) that were deactivated in the driver model. Because the MODS model had undergone more rigorous parameter testing with detailed data, it was decided to incorporate its parameter values into the integrated model, thus overriding the driver model's global settings. Fortunately (and perhaps surprisingly), this decision had no apparent adverse effects on the normal operation of the driver model, which proved rather robust to the different parameter settings and activated learning mechanisms.

Model Simulations

The driver model was made to interact with a driving simulation that mimicked the critical elements of the Alm and Nilsson (1995) car-following task. A total of 15 simulations were run: 5 runs in the *No-Task* condition without a secondary task, 5 runs in the *Task-SS* condition with the Single-Step model performing the secondary task, and 5 runs in the *Task-GS* condition with the Group-Step model performing the secondary task. Each simulation generated a detailed behavioral protocol at a rate of roughly 13 Hz including all relevant control and environmental data as well as marks for the start and end of the braking events.

Model Predictions and Empirical Results

We can now compare the model predictions with Alm and Nilsson's (1995) empirical results. It should be emphasized that the present study does not involve typical parameter estimation for fitting the model to data; rather, it centers on *a priori* predictions by simply integrating the models, running simulations, and checking the results. The goal of the study is thus to predict the effects of the secondary task on driver performance primarily in qualitative terms and, secondarily, in quantitative terms as much as possible.

Brake Reaction Time

The first and more important aspect of driver performance examined is drivers' *brake reaction time*, or the time lapse between the start of the lead vehicle's braking and the initiation of braking by the driver. Figure 1(a) shows the reaction times (means and standard deviations) predicted by the model for the *No-Task*, *Task-SS*, and *Task-GS* conditions. While the reaction time for the no-task condition was approximately 2.5 s, the reaction times for both task conditions were significantly higher at roughly 2.9 s, and thus the model predicts a significant impact of the secondary task on drivers' braking reaction.

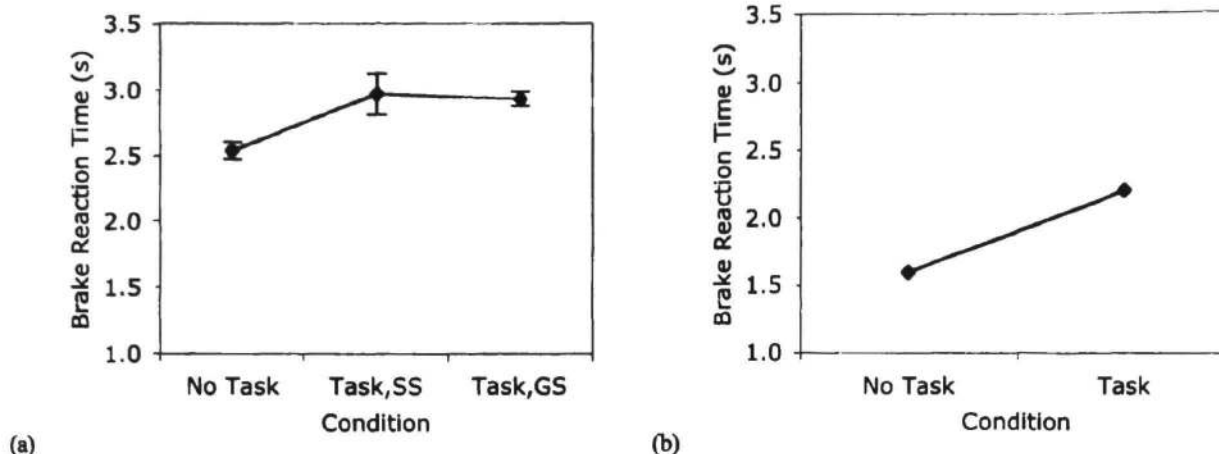

Figure 1: Brake reaction times for (a) model simulations and (b) empirical data.

Figure 1(b) shows the empirical results for brake reaction time. These results also show a clear (and significant) task effect, with an increase of reaction time from 1.6 s without the task to 2.2 s with the task. The model and empirical results therefore correspond well qualitatively. Quantitatively, the model predictions are roughly .7–.9 s too high; this discrepancy may be attributed to the fact that the model uses only distance of the lead vehicle to determine how it accelerates and decelerates, whereas the human drivers could also attend to the lead vehicle's brake lights, providing the latter with additional cues to initiate braking.

Lateral Deviation

The second aspect of performance is one of the most common measures for driver distraction studies, namely the *lateral deviation* of the driver's vehicle — defined as the root-mean-squared error of the vehicle's center with the central position in the lane. Figure 2 shows the model predictions for lateral deviation in the three conditions.

Figure 2: Lateral deviation for model simulations.

Interestingly, the SS model predicts no effect of secondary task on lateral deviation. However, the GS model predicts quite a large effect of approximately 50 cm.

Alm and Nilsson (1995) do not report specific numbers for lateral deviation; however, they do report a statistical analysis on these data that found no significant task effect on lateral deviation (against their original hypothesis). The predictions of the SS model thus support their results, demonstrating how closely interleaved multitasking can, in certain situations, have no significant effect on lateral deviation. On the other hand, the predictions of the GS model show that less conservative, "grouped" multitasking can draw cognitive attention away from the driving task enough to create a significant effect.

Headway Distance

The third aspect of performance is *headway distance*, or the distance between the driver's vehicle and the lead vehicle. While headway was maintained at 75 m during normal conditions, the lead vehicle's braking would greatly reduce this headway until the driver has a chance to react. Figure 3(a) shows the model predictions for the *minimum* headway distance, a measure of how close the driver's vehicle came to the lead vehicle. In all three conditions, the model exhibited a minimum headway of approximately 35 m.

Figure 3(b) shows the minimum distances reported in the empirical study. Here there is a clear task effect: the headway decreases significantly in the presence of the secondary task. Thus, the model predictions are not supported for the distance-headway measure. It seems that although the model clearly reacts later in the task condition, it also compensates for the late reaction by braking harder, thus eliminating any potential task effect.

Conclusions

The SS model's *a priori* predictions matched two of the three measures qualitatively, correctly predicting an effect on reaction time but no effect on lateral deviation. Given the ambiguity in the driver-distraction literature on when such

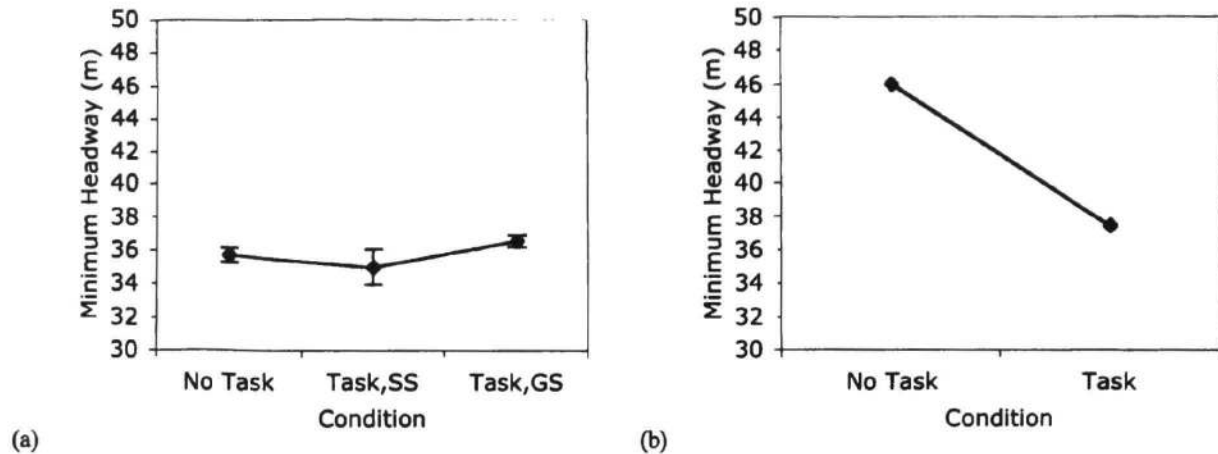

Figure 3: Minimum headway distance for (a) model simulations and (b) empirical data.

effects may occur, this is a strong result that demonstrates the model's ability to predict distraction for certain measures and not others. However, the model did not predict the effect on minimum headway, perhaps due in part to the fact that the headways were large enough that human drivers felt no dire need to closely maintain headway.

The GS model's predictions were not as good, failing to predict the absence of an effect on lateral deviation. Its failing indicates one shortcoming of this work: although the integration of models is mostly straightforward, there remain too many degrees of freedom with respect to how models can and should multitask. Combating this problem requires a more rigorous treatment of multitasking, and cognitive architectures such as ACT-R show promise in being able to account for such a process. In particular, architectures provide an opportunity to handle multitasking at the "software level" through new models implemented as production rules and/or at the "hardware level" through changes to the architecture's inner mechanisms. Recent models of complex dynamic tasks, though not yet the comprehensive models required for the long term, have already demonstrated good ability in capturing some aspects of multitasking (e.g., Chong, 1998; Jones et al., 1999).

As a related point, cognitive architectures also have the substantial benefit of facilitating re-use of models, parameters, and other components from one model to another. This study exhibits this property primarily in the re-use of two existing models for predicting distraction. However, it also opens the door to predicting numerous other aspects of behavior. For instance, Lovett et al.'s (2000) treatment of their MODS model includes an investigation of how ACT-R's *W* parameter can represent individual differences in working memory capacity. Because their work addresses mechanisms fundamental to the architecture, it can carry over directly into further investigations of the effects of capacity differences on driver distraction or even just on driving itself. This ability to share ideas and mechanisms across domains offers enormous explanatory and predictive power to architectural models in new and existing domains of study.

Acknowledgments

Many thanks to Marsha Lovett for providing the MODS model code and to Christian Lebiere, John Anderson, and Lynne Reder for helpful comments and suggestions.

Abstract

Two experiments investigated the impact of problem order and problem sequencing on performance. In experiment 1 subjects were either presented with a suitable or an unsuitable presentation sequence where they were free to deviate from. Presentation sequence had an impact on performance and rearranging problems improved performance for high prior-knowledge subjects whereas low prior-knowledge subjects' performance deteriorated. Experiment 2 yielded evidence that effects of problem sequence have to be triggered by directing subjects' attention to comparing problems before working on them. Results are discussed within the framework of analogical transfer.

The Impact of Problem Order

In this paper we investigate the impact of problem order on performance when solving a sequence of mathematical problems. It has to be noted that effects of sequencing *to-be-learned materials* have been widely studied in the Sixties and the Seventies (Posner & Strike, 1976; Van Patten, Chao, & Reigeluth, 1986 for an overview), whereas effects of sequencing *to-be-solved problems* have received only little attention. Sequence effects are said to occur when performance on problem *B* varies depending on whether problem *A* had been performed before or not. This influence of solving problem *A* on performance for problem *B* should be specific to problem *A*, i.e., solving a problem *C* before *B* should not necessarily lead to the same performance for *B* as solving problems in the sequence *AB*. This specificity assumption distinguishes sequence effects from mere training or position effects.

Sequence effects can be analyzed as the result of two distinct cognitive processes that take place in succession, namely, learning and transfer. *Learning* refers to a change in the cognitive system of the problem solver (i.e., newly generated or modified knowledge structures) that occurs due to solving a problem *A*. *Transfer* refers to the transmission of these newly generated or modified knowledge structures to a subsequent problem *B*.

The two most prominent approaches to transfer are Singley and Anderson's rather analytical theory on transfer of cognitive skill (Singley & Anderson, 1989) and the more holistic theories of transfer by analogy (Gentner, 1983; Gick & Holyoak, 1980).

Singley and Anderson's basic assumption is that a problem is more likely to be solved the more declarative and/or procedural knowledge elements necessary to solve that problem are already known by the problem solver. Therefore, transfer among problems should increase with the number of elements being shared by the problems (Thorndike & Woodworth, 1901). Furthermore, because transfer is based on the extent of overlap between the knowledge structures necessary to accomplish two tasks a symmetrical relation between problem *A* and *B* is assumed. (Pirolli & Recker, 1994; Singley & Anderson, 1989). It is important to note, however, that sequence effects may be asymmetrical, i.e., a problem sequence *AB* might result in a different performance than a problem sequence *BA*. This asymmetry is due to the fact that the amount of what has been learned in the first place and can therefore be transferred to a succeeding problem may differ among problems. For instance, working on a difficult problem at first may result in less learning than starting with a simpler problem.

Transfer by analogy is described as the transmission of knowledge from one problem-solving situation (the source) to a target problem and consists in a number of different processes. In order to solve a target problem first a suitable source problem has to be retrieved from memory. Next, elements of the source problem have to be mapped onto the target problem. Finally, based on these mappings a solution for the target problem is generated. Research on analogy has demonstrated that structural similarity among source and target is the most important determinant of successful transfer and that this transfer is often restricted to situations where source and target are structurally equivalent. If there are structural differences between problems subjects often fail to adapt a source problem's solution to fit the requirements of the target (Reed, Dempster, & Ettinger, 1985).

With regard to sequence effects it can therefore be assumed that performance for a specific problem should improve if one solves structurally similar problems in succession. Contrarily, switching between unrelated problems might impede problem solving because this increases the probability that unsuitable preceding problems are used as sources to guide later problem solving.

Whereas there is only preliminary evidence for this assumption concerning structural similarity in a study by Novick (1988), two problem-solving studies have

investigated the effects of the second aforementioned factor that may influence the suitability of a problem sequence, namely a problem's difficulty. Reed, Ernest, and Banerji (1974) obtained no effect of problem order when studying transfer from the easier Missionary-Cannibals problem to the more difficult Jealous-Husbands problem and vice versa. Subjects who had been acquainted with the similarity relations among the problems, however, solved the problems faster in the difficult-easy sequence. Furthermore, Cook (1937) found that a difficult-easy sequence led to better performance when working on pyramid puzzles. Based on these two results it could be argued that solving difficult problems before easier ones should result in better performance than a reversed sequence. However, this may only hold for knowledge-lean problems (in the sense of VanLehn, 1989) whereas for knowledge-rich problems solving an easy problem first may support solving more difficult problems of the same problem category. This should be the case because more difficult problems often share structural elements with the easier problems. Therefore, mastering these problem components in the easier problems provides practice for solving the more difficult problems entailing these components among other new elements. This idea of mastering (subordinate) parts of a skill before proceeding to more difficult demands is in line with proposals made for the design of instructional curricula (cf. Schoenfeld, 1985; Van Patten et al., 1986).

To summarize, problem sequences that are ordered with respect to the structural similarity of the problems (similar problems being solved in succession) and with respect to the difficulty of the problems (easy-to-difficult) should result in better performance compared to either reversed or to random sequences.

Sequencing as a Metacognitive Strategy

In experimental problem-solving settings subjects are usually asked to maintain a given order when solving multiple problems whereas in more self-controlled situations they might be given the opportunity to decide on a problem sequence by themselves. In this case the question whether problem solvers strategically rearrange problems in order to improve their performance gains increasing importance.

Problem sequencing can be seen as a process that is exactly reverted to the retrieval process in analogical problem solving. In analogical problem solving a backward search is conducted to find a source problem in memory whose solution can be adapted to the to-be-solved target. Contrarily, sequencing may be described as a forward search to decide on the next to-be-solved problem (target) for which the solution of the problem being solved most recently (source) can be adapted. Conceptualizing problem sequencing in accordance with the retrieval process in analogical problem solving brings about some major advantages. In particular, findings on analogy may be used to derive hypotheses concerning problem sequencing as a metacognitive problem-solving strategy.

First, the *propensity to sequence problems* should depend on whether subjects are aware of the fact that different problem sequences may be associated with different

performance outcomes and that applying knowledge used to solve one problem when approaching a next problem might foster performance. However, research in analogical problem solving has repeatedly shown that subjects often fail in using previous problem-solving experiences spontaneously when solving new problems (Reed et al., 1985) and that they need to be provided with hints in order to ensure analogical transfer (Gick & Holyoak, 1980). Additionally, the costs that result from searching for a suitable target problem that is to be solved next have to be less than the benefits that are achieved by rearranging problems deliberately. This reasoning is in line with assumptions made by Novick (1988) or Reed et al. (1974) concerning the retrieval process in analogical problem solving. For instance, Reed et al. (1974, p. 448) postulate that "the total time to retrieve, translate, and use analogous information to find an operator should be less than the total time to find the same operator without using information from the previous problem."

Second, the *successfulness of rearranging problems* depends on whether subjects are able to identify a suitable problem sequence by themselves. In terms of analogical problem solving this relates to the question of whether subjects are able to retrieve a source problem that is structurally similar to the target. With respect to this issue research has demonstrated that subjects often face difficulties in recognizing structural problem features and that they are often misled by surface similarities of the problems (Holyoak & Koh, 1987; Ross, 1987). Novick (1988) demonstrated that the ability to retrieve a structurally similar analogue interacts with subjects' domain-specific prior knowledge with experts being more likely to find a suitable source problem than novices are. Therefore, it can likewise be assumed that the quality of problem sequencing might interact with subjects' prior knowledge in a way that only high prior-knowledge subjects benefit from self-determined sequences whereas the additional freedom of rearranging test problems might even be harmful for less advanced subjects.

In order to investigate the impact of problem order and problem sequencing on problem-solving performance two experiments were conducted. In experiment 1 subjects were provided with one of two different presentation sequences that they were free to rearrange. Contrarily, subjects in experiment 2 were confronted with predefined problem orders they could not deviate from in order to find out whether differences in problem-solving performance can still be observed when subjects are not made aware of the potential impact of problem order.

Experiment 1

Method

Participants Subjects were 76 students (49 female, 27 male) of the University of Goettingen, Germany, who participated for course credit or payment. Average age was 22.67 years.

Materials and procedure For experimentation the hypertext-based learning and problem-solving environment HYPERCOMB was used (Gerjets, Scheiter, & Tack, 2000) which contains a short introduction to the domain of combinatorics followed by a learning phase where subjects can acquire knowledge by studying worked-out examples for six problem types.

Permutation problems are about finding out the number of possibilities of bringing all elements of a set into a distinctly ordered arrangement. *Variation problems* deal with the number of possibilities for selecting a subset of elements out of a set of elements in a distinct order. *Combination problems* are about the number of possibilities for selecting a subset of elements out of a set of elements without regard to the order. All three kinds of problems can be further distinguished as being *with* or *without replacement* yielding six problem types. Replacement indicates whether the set contains undistinguishable elements or whether elements can be selected more than once, respectively. Similarity among permutations, variations, and combinations can be described with respect to the number of permutations necessary to solve a specific problem. These similarity relations among the problem types are not only expressed at this conceptual level but are also reflected at the computational level in the graded complexity of the formulas needed to solve the problems. Therefore, one can characterize transfer relations among problem types in combinatorics that are based on the overlap at the computational and conceptual level. According to this task analysis a problem sequence ranging from permutations to variations and ending with combinations should be suited best for problem solving as the problem types that are most structurally similar to each other are presented in succession.

In HYPERCOMB each problem type was illustrated by abstract information concerning its structural features and two worked-out examples. One example explained the basic application of the solution principle and the other example illustrated a more complicated situation where the solution principle in question had to be applied twice in order to solve a problem. Subjects could decide which instructional materials they wanted to study and when they wanted to quit the learning phase. In the subsequent test phase the instructional material was no longer available and subjects were asked to work on six test problems. For those test problems the solution principles which had been taught before had to be applied once for easy problems or twice for difficult problems (figure 1).

When starting the test phase subjects were informed that they would have to solve six test problems listed on a single page. They were asked to study all test problems carefully before selecting a problem they wanted to start working on. Subjects were further informed that they could solve the test problems in any order they wanted. Whenever subjects had solved a problem the initial page with all six problems was presented (including the ones already being solved) and subjects were asked to select the next problem. In order to prevent subjects from solving a problem twice solved problems could no longer be retrieved.

Easy problem: A lighthouse can flash in six different colors (red, yellow, green, blue, orange, pink) from which colors are randomly chosen to form a flare. Each flare contains two colors in succession and none of the colors can appear twice in one flare. What is the probability that the lighthouse will send a red-orange flare, i.e. it will first flash red and then flash orange?

Difficult problem: At a soccer game there are two dressing rooms for the two teams. The kickers from Oxford wear T-shirts with uneven numbers from 1 to 21 and Manchester has even numbers from 2 to 22. As the aisle from the dressing rooms is very narrow only one player at a time can enter the field. The players of the two teams leave their rooms alternately with a player from Oxford going at first. What is the probability that the first five players who enter the field have the numbers five, two, thirteen, eight, and one (i.e., the first has the number five, the second has got the two and so on)?

Figure 1: Easy and difficult test problems of problem type "variation without replacement"

Design and dependent measures As a first between-subjects variable the presentation sequence of the six test problems was manipulated. In the *suitable sequence* the problems were presented in the postulated optimal order - permutation, variation, and combination with an easy-to-difficult sequence within each problem type. In the *unsuitable sequence* variations were followed by permutations and combinations; within problem types difficult problems were presented first. As a second between-subjects variable we used subjects' *domain-specific prior knowledge* which was controlled by means of a multiple-choice questionnaire at the beginning of the experiment. A median split within the two sequence conditions was conducted to distinguish between subjects who possessed low or high prior knowledge.

As performance measures subjects' error rates for easy and difficult test problems and problem-solving time were registered. For each of the six test problems subjects had to identify the correct solution principle and the values of four variables in a multiple-choice form. No calculations had to be made. A maximum of two errors was assigned for the identification of the principle and one error was assigned for each wrong answer concerning the variable values resulting in a maximum of six errors for each problem. Additionally, subjects were distinguished as to whether they rearranged problems by deviating from the given presentation sequence or not. Finally, in order to ensure that subjects were equivalent with respect to their learning behavior the example-processing time was registered and analyzed as well.

Results and Discussion

A first comparison by means of an ANOVA (presentation sequence \times prior knowledge) revealed no significant differences with regard to either pretest errors ($F(1,72) = 1.29$; $MSE = 83.10$; $p > .25$) or overall example-processing time ($F < 1$) between the presentation sequences (table 1).

In order to analyze subjects' performance on the six test problems and on subjects' problem-solving time as a function of presentation sequence, prior knowledge, and sequencing behavior a third factor was entailed in the

analysis. This factor indicated whether subjects had kept the presentation order while working on the problems or whether they had deviated from it (i.e., sequencing behavior). Additionally, we used example-processing time as a covariate because this turned out to be a very important factor for predicting subjects' performance and because this measure was characterized by a high variability within each of the two presentation sequence conditions. This resulted in a three-factor ANCOVA (presentation sequence \times prior knowledge \times sequencing behavior) that was deployed for analyzing performance on easy and difficult problems as well as for problem-solving time. We will first report the effects for presentation sequence and prior knowledge (table 1) before having a closer look to the impact of subjects' sequencing behavior on performance (figures 2a, 2b).

Table 1: Performance (in %) and time data (in sec) as a function of presentation sequence and prior knowledge

Presentation sequence	Suitable sequence		Unsuitable sequence	
Prior knowledge	High	Low	High	Low
Pretest errors	44.3	74.1	47.9	75.2
Example-processing time	650	547	612	532
<i>Problem-solving errors:</i>				
- Easy problems	12.0	10.0	16.2	21.8
- Difficult problems	37.5	46.4	43.2	46.7
<i>Problem-solving time</i>				
	1075	998	1066	1052

Effects of presentation sequence and prior knowledge

With regard to the number of problem-solving errors for easy test problems subjects who were presented with the suitable sequence outperformed subjects who worked in the unsuitable sequence condition as predicted ($F(1,72) = 5.02$; $MSE = 244.29$; $p < .05$) whereas there was no effect for difficult test problems ($F(1,72) = 1.50$; $MSE = 371.93$; $p > .20$). None of the effects for prior knowledge nor the interactions between presentation sequence and prior knowledge were significant (all F s < 1). With regard to problem-solving time there were no effects for either presentation sequence or prior knowledge nor was there an interaction between the two factors (all F s < 1). To summarize, the superiority of the suitable presentation sequence could be demonstrated for performance on easy problems independently of subjects' prior knowledge.

Sequencing behavior A question that has yet been left unanswered is whether subjects rearrange problems when being confronted with an unsuitable presentation sequence and how their sequencing behavior contributes to problem-solving performance. Analyzing the percentage of subjects who deviated from the presentation sequence an ANOVA (presentation sequence \times prior knowledge) clearly revealed that subjects reacted sensitively to the quality of the presentation sequence by deviating more often from the unsuitable sequence than from the suitable one ($F(1,72) =$

9.79; $MSE = 0.23$; $p < .01$; suitable sequence/ high prior knowledge: 21% sequencers; suitable sequence/ low prior knowledge: 35% sequencers; unsuitable sequence/ high prior knowledge: 65% sequencers; unsuitable sequence/ low prior knowledge: 60% sequencers). Sequencing behavior was unaffected by subjects' prior knowledge - with the main effect and the interaction both being meaningless (both F s < 1). Deviations from the given presentation sequence were mainly caused by subjects' preference to work on easy problems before approaching the more difficult ones - regardless of structural similarities among easy and difficult problems.

Effects of sequencing With regard to the impact of sequencing on performance for easy problems an expected pattern of results could be obtained (figure 2a). There was no main effect of sequencing behavior ($F < 1$), however, sequencing behavior interacted with subjects' prior knowledge in that high prior-knowledge subjects improved by rearranging problems whereas low prior-knowledge subjects' performance even deteriorated ($F(1,72) = 5.20$; $MSE = 244.29$; $p < .05$). Although this effect seemed to interact with presentation sequence the triple interaction was not significant ($F(1,72) = 1.31$; $MSE = 244.29$; $p > .20$), nor was there an interaction between presentation sequence and sequencing behavior ($F < 1$).

Figure 2a: Problem-solving errors for easy test problems as a function of subjects' sequencing behavior, presentation sequence, and prior knowledge

The effects for problem-solving performance on difficult test problems was different (figure 2b). Performance improved slightly by rearranging problems ($F(1,72) = 2.99$; $MSE = 371.93$; $p < .10$), whereas there were no interactions with prior knowledge or presentation sequence (all F s < 1).

Additionally, there was no main effect for sequencing behavior on the overall time subjects needed to solve all six test problems ($F < 1$) nor were there any interactions with either presentation sequence or prior knowledge (all F s < 1.78 and all p s $> .15$).

Experiment 2

Method

Participants Subjects were 78 students (48 female, 30 male) of the University of Goettingen who participated for course credit or payment. Average age was 24.1 years.

Materials and procedure The same learning and problem-solving material as in experiment 1 was used. However, the procedure was varied. The problems were presented in predefined sequences that subjects could not deviate from. Subjects started working on problem 1 in the sequence. After subjects had solved a problem the next problem was automatically presented. Subjects did not see any of the test problems before this automatic presentation. No return to preceding problems was possible.

Design and dependent measures As a first between-subjects variable the *presentation sequence* was varied by presenting the problems according to the same orders as in experiment 1. As a second between-subjects variable subjects' *domain-specific prior knowledge* was used. As performance measures subjects' error rates and problem-solving time were registered. Additionally, example-processing time was measured.

Results and Discussion

A first comparison by means of an ANOVA (presentation sequence x prior knowledge) revealed no significant differences with regard to prior knowledge between the two presentation sequences ($F < 1$). The effect of presentation sequence for example-processing time however almost reached statistical significance ($F(1,74) = 2.49$; $MSE = 1555590.10$; $p > .10$). Therefore, this variable was again used as a covariate in all further analyses (table 2).

Table 2: Performance (in %) and time data (in sec) as a function of presentation sequence and prior knowledge

Presentation sequence	Suitable sequence		Unsuitable sequence	
	High	Low	High	Low
Priest errors	46.8	74.7	47.2	70.8
Example-processing time	722	678	539	579
<i>Problem-solving errors:</i>				
- Easy problems	16.1	21.4	15.8	18.1
- Difficult problems	35.9	49.3	42.4	50.8
<i>Problem-solving time</i>	977	897	830	849

There was no main effect for prior knowledge on performance for easy test problems ($F(1,74) = 1.04$; $MSE = 258.55$; $p > .30$), whereas it positively influenced performance on difficult test problems ($F(1,74) = 7.20$; $MSE = 321.39$; $p < .01$). Most interestingly, there were no effects

Figure 2b: Problem-solving errors for difficult test problems as a function of subjects' sequencing behavior, presentation sequence, and prior knowledge

To summarize, we found that the order in which problems are solved had an impact on problem-solving performance for *easy test problems* in that a sequence where problems were arranged according to their structural similarity and difficulty was superior to a presentation sequence not making use of this principles. Additionally, we could demonstrate that subjects tried to make use of this effect of problem sequence by rearranging problems when they were presented in an unsuitable way. However, improvements due to problem sequencing were predominant for subjects with high prior knowledge who are more likely to identify structural similarities among problems. On the contrary, low prior-knowledge subjects' performance deteriorated when they deviated from a given order of problems if these problems were unsuitably arranged.

However, the pattern of results obtained for *difficult test problems* yielded evidence for some additional speculations. In particular, sequencing improved performance on difficult test problems independently of whether subjects deviated from a suitable or an unsuitable sequence. Subjects who rearranged problems may have followed the instruction to first read all problems carefully before selecting a problem to work on. This may have focussed subjects' attention on comparing test problems and thereby displaying a deeper processing which in turn improved performance. This interpretation is related to the question on whether subjects spontaneously notice problem similarities by themselves or whether they need hints in order to make use of potential analogues relations among test problems. If the latter is true, sequence effects should only be observable when subjects are asked to process test problems thoroughly as in this experiment, but should be absent when problems are presented in predefined orders without any further instructional support. In order to address this issue a second experiment was conducted.

of presentation sequence and no interactions between the two factors for any of the two performance measures (all $F_s < 1$). Additionally, presentation sequence had barely no impact on problem-solving time ($F(1,74) = 1.89$; $MSE = 46501.88$; $p > .10$). The main effect for prior knowledge as well as the interaction were not significant ($F_s < 1$). The interpretation of these results is straightforward. Simply presenting test problems in a suitable order is obviously not sufficient to improve problem-solving performance.

General Discussion

In experiment 1 a problem sequence where problems were arranged according to their structural similarity and their difficulty outperformed a problem sequence where these sequencing principles were reversed. Experiment 2 demonstrated that sequence effects only occurred when subjects were instructed to process problems carefully before working on them. This is in accordance with findings on analogy that spontaneous transfer is hard to achieve. Instead, subjects need hints that relations between problems are important in order to benefit from a suitable sequence.

Additionally, we demonstrated that subjects try to make use of this effect of problem sequence by rearranging unsuitable problem sequences. However, only subjects with high prior knowledge who are more likely to identify structural similarities seem to benefit from problem sequencing. In contrast to that, subjects with low prior knowledge do not seem to possess the skills necessary for identifying a more suitable problem sequence than the one they are initially presented with.

Several issues will be addressed in forthcoming experiments. First, the question arises whether subjects' ability to sequence problems as well as spontaneous transfer within predefined problem sequences can be fostered by deliberately directing subjects' attention to structural similarities of the problems. Second, it is of interest whether other findings of analogy-based research can likewise be transferred to problem sequencing. In particular, we want to investigate whether not only the retrieval process in analogical problem solving but also problem sequencing is vulnerable to effects of superficial similarities among problems. Third, we aim at distinguishing sequence effects that occur due to structural similarity versus sequence effects that are merely caused by the relative difficulty of problems. Additionally, a more-fine grained analysis of subjects' sequencing strategies with regard to this distinction seems promising. The results of experiment 1 provide preliminary evidence that subjects mainly sequenced problems according to their relative difficulty without paying attention to their structural interrelationships. In domains where structural similarities among problems are more evident - like algebra word problems - sequencing behavior may be quite different. Therefore, a series of experiments is currently being conducted using algebra problems.

Acknowledgements

Stochastic Independence between Recognition and Completion of Spatial Patterns as a Function of Causal Interpretation

Wolfgang Schoppek (wolfgang.schoppek@uni-bayreuth.de)

Department of Psychology, University of Bayreuth
D-95440 Bayreuth, Germany

Abstract

A common view in the research on dynamic system control is that human subjects use exemplar knowledge of system states – at least for controlling small systems. Dissociations between different tasks or stochastic independence between recognition and control tasks, have led to the assumption that part of the exemplar knowledge is implicit. In this paper, I propose an alternative interpretation of these results by demonstrating that subjects learn more than exemplars when they are introduced to a new system. This was achieved by presenting the same material – states of a simple system – with vs. without causal interpretation. If subjects learned exemplars only, then there should be no differences between the conditions and stochastic dependence between various tasks would be expected. However, in an experiment with $N=40$ subjects the group with causal interpretation is significantly better at completing fragmentary system states and in judging causal relations between switches and lamps, but not in recognizing stimuli as studied. Only in the group without causal interpretation, the contingency between recognition and completion was close to the maximum memory dependence, estimated with Ostergaard's (1992) method. Thus, the results resemble those of other studies only in the condition with causal interpretation. The results are explained by the assumption that subjects under that condition learn and use a second type of knowledge, which is construed as a rudimentary form of structural knowledge. The interpretation is supported by a computational model that is able to reproduce the set of results.

Dynamic system control (DSC) is a paradigm of great interest for applied and basic research likewise. In applied contexts, researchers address questions about how human operators learn to operate new technical systems efficiently, how training should be designed, or what errors operators are likely to commit. In basic research, DSC is one of the paradigms for studying implicit learning. It has been argued that subjects control dynamic systems predominantly with exemplar knowledge about system states, part of which is considered implicit (Dienes & Fahey, 1998). This conclusion was derived from studies with systems characterized by small problem spaces, such as the "Sugar Factory" (a dynamic system with one input and one output variable, connected by a linear equation; Berry & Broadbent, 1988). However, studies with more

complex systems have delivered evidence that structural knowledge (i.e. knowledge about the variables of a system and their causal relations) can be more effective for controlling these systems (Vollmeyer, Burns, & Holyoak, 1996; Funke, 1993), although it is not easy to apply and use this type of knowledge (Schoppek, 2002). But even for small systems, the question about what type of knowledge is learned in an implicit manner, is still open. Simulation studies that have proven the sufficiency of exemplar knowledge for controlling the Sugar Factory (Dienes & Fahey, 1995; Lebiere, Wallach, & Taatgen, 1998) have as yet not reproduced effects that point to implicit learning. An example of such effects is the stochastic independence between recognition of system states of the Sugar Factory as studied and performance in one-step control problems, found by Dienes & Fahey (1998). Since exemplar knowledge is typically construed as explicit rather than implicit, it cannot account for these dissociations.

This paper addresses the question if a rudimentary form of structural knowledge is acquired in addition to exemplar knowledge, albeit implicitly or explicitly. The different use of exemplar knowledge and structural knowledge in different tasks can explain dissociations between tasks. The basic strategy for separating the two

Figure 1: Problem space of the Switches & Lamps system; the states with white triangles were studied in the learning phase

knowledge types rests on using material that can be interpreted as states of a system or simply as spatial patterns. Therefore, I designed a system consisting of four lamps operated by four switches. Each switch affects one or two lamps. Two of the effects were negative, which means that the corresponding lamp is switched off when the switch is turned on. The problem space of 16 possible states is depicted in Figure 1. Subjects under both conditions (causal interpretation vs. no causal interpretation) are shown possible states and asked to memorize them.

In a previous experiment with that paradigm (Schoppek, 2001), I found positive effects of causal interpretation on recognition of patterns as studied and on causal judgment. The effects were attributed to a preliminary form of structural knowledge, namely associations between switches and lamps, acquired by the group with causal interpretation. This knowledge enables subjects to reconstruct a system state in cases where no exemplar representation of the state can be retrieved. The pattern of results was reproduced by a computational model that instantiates these assumptions. The model is written in ACT-R (Anderson & Lebiere, 1998), a cognitive architecture that distinguishes between subsymbolic and symbolic levels of processing, with associative learning residing on the subsymbolic level.

The experiment also delivered some hints that there was stochastic independence between recognition of states as studied and a completion task in the group with causal interpretation, but dependence in the other group. Again, this supports the assumption that more than one knowledge type is used in the causal condition. However, to judge the empirical contingency between tasks, it should be compared with the maximum possible memory dependence, estimated with a method proposed by Ostergaard (1992). This method requires answers to nonstudied items in the completion task, but all items that could be reasonably used in that task (i.e. all possible system states) have been studied in Schoppek (2001). Therefore in the present experiment, subjects studied only a subset of system states. This fact implies a different prediction for recognition of states as studied: The set of possible states and the set of studied states were identical in the previous experiment, whereas they are different in the present experiment. This makes the strategy of reconstructing system states susceptible to errors, because classifying any possible state as studied would result in many false alarms. Thus in the present experiment, I expected no differences in recognition performance between the two conditions.

Experiment

The experiment started with a learning phase where subjects saw 60 system states in intervals of four seconds. The sequence consisted of ten out of sixteen

possible system states that were repeatedly shown in a "natural" order, i.e. only one switch changed its status from item to item. The ten states were selected such that all causal relations between switches and lamps could be concluded from them. All subjects were instructed to memorize the "states" (in the condition "causal interpretation" or ci group) or the "patterns" (in the condition "no causal interpretation" or nci group). The learning phase was followed by a speeded recognition task. 20 items, including the ten studied states, six nonstudied states, and four impossible states, had to be classified as studied or nonstudied. Next, subjects worked on the completion task, where they saw arrays of switches in certain states and were asked to complete the patterns by clicking on the correct lamps. All possible states, except the one where no switch is on, were administered. Then the subjects of the group without causal interpretation were debriefed about the meaning and the causal nature of the material. Finally, in a causal judgment task, subjects were asked to estimate the causal strength of all 16 combinations between switches and lamps on a scale ranging from -100 (strong negative relation), through 0 (no relation), to 100 (strong positive relation). N=42 students from the University of Bayreuth, participated in the experiment. One subject had to be excluded because of erroneous administration of the tasks; one other subject was excluded because he had misunderstood the instructions.

I expected medium to large effect sizes ($d = 0.65$) in this experiment. With the given sample size of $n=20$ for each group, the α -level is set to $p<0.1$ to get an acceptable power of 0.67. All significance tests were two-tailed¹.

Recognition

I expected no differences in discrimination between the two groups. This can be explained as follows. For the nci group, conditions are not much different to the previous experiment (Schoppek, 2001), except that fewer states were shown and each state was shown equally often. In the ci group, however, the fact that not all possible system states were shown in the learning phase is expected to lead to some confusion. Subjects who know about the causal structure of the material may recognize nonstudied system states as regular states and mistake them as studied. Thus, in contrast to the previous experiment, there is no advantage of knowing the causal structure. It is hard to predict if subjects use the strategy of reconstructing system states at all. An indicator for using the strategy is a longer response time.

¹ The power analysis was calculated with the G-Power program by Faul & Erdfelder (1992).

As expected, discrimination indices for recognition (calculated according to the two-high-threshold model by Snodgrass & Corvin, 1988) are almost equal in both groups (ci: $d=0.46$, $s=0.19$; nci: $d=0.43$, $s=0.17$; $t=0.53$). However, mean response times rt for hits are significantly longer in the ci group (ci: $rt=2325$ ms, $s=1159$ ms; nci: $rt=1699$ ms, $s=513$ ms; $t=2.21$, $p<0.05$). This result, including the difference in the standard deviations, closely replicates the findings of Schoppek (2001). It supports the assumption that at least some of the subjects in the ci group used the strategy of reconstructing system states on the basis of structural knowledge.

Completion

Since all possible system states had to be completed in this task, I expected the ci group to be better than the nci group. Subjects in the latter group have only a small chance to complete nonstudied items correctly.

Performance in the completion task is measured by summing up deviations from the correct solution over all items (variable td). For each lamp, a deviation is counted when the lamp is in the wrong state, resulting in a maximum deviation of four per item. Thus, the total deviation td ranges between 0 and 60 ($4 \cdot 15$ items). The expected deviation for chance performance is 30 ($0.5 \cdot 4 \cdot 15$). As expected, there is a significant difference in total deviation between the groups: The ci group deviates less from the correct solutions than the nci group (ci: $td=21.9$, $s=6.7$; nci: $td=25.3$, $s=4.6$; $t=1.88$, $p<0.1$). Generally, performance in the completion task was low: In terms of correct items, the ci group solved an average of 3.9 items (26%), the nci group an average of 2.9 items (19%). However, these values are close to those found by Dienes and Fahey (1998) in their one-step control problems with the Sugar Factory.

Causal Judgment
